Vascular abnormalities in TA can be imaged by conventional angiography, MRI, MRA, CT angiography, or ultrasonography[26,76,78,104,113] (Figure 88-10, Figure 88-11, and Figure 88-12). Each imaging technique has advantages and disadvantages (Table 88-10). The earliest detectable abnormality in TA is thickening of the vessel wall from inflammation. MRI, ultrasonography, and, to a lesser degree, CT can detect this early vessel wall thickening. Conventional angiography is invasive and provides the least sensitive method for visualizing wall thickness; however, conventional angiography is the "gold standard" for precisely delineating the stenoses, occlusions, and aneurysms that characterize the latter stages of TA. Also, only conventional angiography allows the direct measurement of central arterial blood pressure, which may be otherwise unobtainable in patients with stenotic lesions affecting all four extremities. Although MRA does not provide the same level of detail as conventional angiography, it comes close. Because MRA is not invasive and does not involve ionizing radiation, it has become the preferred imaging method for assessing the extent of vascular involvement and damage, both initially and during follow-up. The role of MRI in assessing disease activity is not clear because vessel wall edema and contrast enhancement have not correlated well with

clinical measures of disease activity.[78] Although PET scanning would be expected to be more sensitive than angiography in the early detection of vascular inflammation that precedes the development of stenoses, its sensitivity may be no greater than MRI. PET scanning has no established role in following disease activity in TA. Indeed, one study of 28 TA patients showed that PET scans did not correlate with clinical, biologic, or MRI assessment of disease activity.[114]

The most common sites of lesions in TA are the aorta (65%) and the left subclavian arteries (93%)[104] (Table 88-11). The left subclavian artery is affected slightly more frequently than the right. Carotid, renal, and vertebral arteries are also commonly affected.[104] Lesions may be stenotic (93%), occluded (57%), dilated (16%), or aneurysmal (7%). Stenotic lesions are approximately four times more common than aneurysmal lesions.[104] Stenotic segments often extend a few centimeters and may be followed by areas of dilation (see Figure 88-10). The majority of patients (53%) have vascular lesions above and below the diaphragm. However, the frequency distribution of aortic lesions varies considerably from country to country.[104]

## Diagnosis and Diagnostic Tests

The ACR has established classification criteria for the diagnosis of TA (see Table 88-8). In clinical practice, the diagnosis of TA is almost always secured by an imaging procedure (see Table 88-10) that demonstrates the characteristic abnormalities of the aorta and its major branches (Figure 88-13). Rarely, the diagnosis is first suggested when a pathologist finds granulomatous inflammation in a section of aorta or other larger artery that was removed or biopsied during a vascular surgery procedure. Unfortunately the diagnosis of TA is often delayed; the delay averaged 44 months in one large series. The most frequent impediment to a speedy diagnosis is a physician's failure to consider TA in the differential diagnosis. Although the rarity of TA helps explain its omission from diagnostic consideration, another reason is that some patients have striking features of inflammation that camouflage or overshadow the somewhat more familiar vascular abnormalities. Indeed, a few patients with TA present chiefly with FUO. Most of these patients have other, albeit subtle, manifestations of TA such as bruits, diminished pulses, unequal arm blood pressures, or aortic regurgitation. In other patients with more striking vascular abnormalities, the physician might be lured into focusing on familiar and dramatic abnormalities such as anemia or thrombocytopenia. Thus, instead of ordering an imaging test that would explain the patient's unequal and low blood pressure in the left arm, the physician mistakenly diverts the patient to a hematologist, gastroenterologist, or oncologist for additional blood tests and procedures that further delay the diagnosis.

Many of these delays can be prevented by remembering that TA should be included in the differential diagnosis of any person younger than 40 years who presents with FUO, aortic regurgitation, hypertension, or unequal or absent pulses. Delays in diagnosis can also be reduced by carefully searching for unequal or absent upper extremity pulses and by listening for bruits not only over the carotid arteries but also above and below the clavicle (for subclavian artery bruits) and over the abdomen and flanks (for renal and other mesenteric artery bruits). Recognizing that anemia and thrombocytosis can be manifestations of active inflammatory disorders such as vasculitis can also help speed the diagnosis of TA.

Once an imaging test demonstrates disease of the aorta or its major branches, the differential diagnosis narrows to a set of disorders that are usually easily differentiated (Table 88-12). Most rheumatic diseases that can affect the aorta are distinguished by their associated features. For example, Cogan's syndrome typically produces ocular inflammation (especially keratitis) and vestibuloauditory dysfunction. The one rheumatic disease that can be difficult to distinguish from TA is GCA (Table 88-13). Usually, the patient's age and the distribution of lesions allow their rapid differentiation, but it can be difficult or even impossible to distinguish TA from GCA in patients 50 years old or older. The similarity of treatment (see subsequent discussion)

**TABLE 88-12** Differential Diagnosis of Takayasu's Arteritis: Other Diseases That Can Affect the Aorta

| Disease Type | Specific Entities |
|---|---|
| Rheumatic | Giant cell arteritis, Cogan's syndrome, relapsing polychrondritis, ankylosing spondylitis, rheumatoid arthritis, systemic lupus erythematosus, Buerger's disease, Behçet's disease |
| Infectious | Syphilis, tuberculosis |
| Other | Atherosclerosis, ergotism, radiation-induced damage, retroperitoneal fibrosis, inflammatory bowel disease, sarcoidosis, neurofibromatosis, congenital coarctation, Marfan's syndrome, Ehlers-Danlos syndrome, $IgG_4$-related systemic disease |

Ig, Immunoglobulin.

**TABLE 88-13** Comparison of Giant Cell Arteritis and Takayasu's Arteritis

| Feature | Giant Cell Arteritis | Takayasu's Arteritis |
|---|---|---|
| Female-male ratio | 2:1 | 8:1 |
| Age range | ≥50 yr | <40 yr |
| Average age of onset | 72 yr | 25 yr |
| Visual loss | 10%-30% | Rare |
| Involvement of aorta or its major branches | 25% | 100% |
| Histopathology | Granulomatous arteritis | Granulomatous arteritis |
| Pulmonary artery involvement | No | Occasionally |
| Renal hypertension | Rare | Common |
| Claudication | Uncommon | Common |
| Ethnic groups with highest incidence | Scandinavian | Asian |
| Corticosteroid responsive | Yes | Yes |
| Bruits present | Minority | Majority |
| Surgical intervention needed | Rare | Common |

diminishes the practical importance of solving this diagnostic dilemma.

Infections of the aorta are rare in most countries. Tertiary syphilis can be excluded by a negative fluorescent treponemal antibody test (the rapid plasma reagin test yields false negative results in approximately one-quarter of patients with late-stage syphilis). Other diseases of the aorta (see Table 88-13) are usually readily separated from TA by the history and physical examination. There has been growing appreciation for a small subset of patients who have noninfectious aortitis that is difficult to categorize. At one center, noninfectious aortitis was found in 8% of patients undergoing resection of the ascending aorta.[115] Although nearly 70% had giant cells, only a minority neatly fit a diagnosis of TA or GCA. A fraction of the cases of thoracic or abdominal aortitis are caused by $IgG_4$-related disease ($IgG_4$-RD), a systemic immune-mediated disease characterized by infiltration of $IgG_4$-bearing plasma cells in the aorta or other affected organs.[116,117]

## Treatment

### Medical Therapy

Corticosteroids are the cornerstone of treatment of active TA.[104, 118, 119] Prednisone, at a dose of 0.5 to 1 mg/kg per day, is indicated for the treatment of active disease. Criteria for active disease include new onset or worsening of two or more of the following: (1) fever or other systemic features (in the absence of other cause); (2) elevated ESR; (3) symptoms or signs of vascular ischemia or inflammation (e.g., claudication, absent pulse, and carotidynia); and (4) typical angiographic lesions.[104] Although approximately 85% of patients with TA present with active disease, approximately 15% do not.[79] The initial dose of prednisone is continued for 4 to 12 weeks before commencing a gradual taper, as is done when treating patients with GCA (see previous discussion). Although nearly two-thirds of patients achieve remission, more than half later relapse. Relapses are especially common when the prednisone dose falls below 20 mg per day.

Relapses can be treated by increasing the prednisone dose or adding an immunosuppressive agent. No agent used for TA has been evaluated in a double-blind, placebo-controlled trial. However, open trials have suggested that weekly oral methotrexate (started at 0.3 mg/kg per week, with the initial dose not to exceed 15 mg/wk) is a moderately effective corticosteroid-sparing drug.[120] Methotrexate can be gradually increased to 25 mg/wk. The emphasis is on lowering the corticosteroid dose because methotrexate seldom allows the elimination of prednisone completely; most patients continue to require at least 5 to 10 mg/day of prednisone. Small open trials have provided even more encouraging results about the effectiveness of anti-TNF inhibitors (etanercept and infliximab) in treating patients with refractory TA.[121-123] These trials emphasize that although these agents can treat TA, they rarely cure it: relapses are likely when the treatment is stopped.[121] Tocilizumab, which blocks the IL-6 receptor, has also been reported effective in individual patients.[89,90,124-126]

Case reports and small series suggest that other corticosteroid-sparing drugs may include azathioprine (2 mg/kg per day), mycophenolate mofetil (2000 mg/day), cyclosporine, tacrolimus, leflunomide, and cyclophosphamide (2 mg/kg per day).[104,119,127] The toxicity of cyclophosphamide in young women is so high that it is rarely used in TA.[104]

Efforts to prevent osteoporosis should be initiated early (as described in Chapter 101). Modifiable risk factors for atherosclerosis—especially hypertension, smoking, inactivity, diabetes, and hyperlipidemia—should be treated maximally.

### Surgical Therapy

TA is the form of vasculitis most frequently requiring revascularization procedures.[104,128,129] Unfortunately, medical therapy rarely reduces or reverses stenotic lesions. Treating stenotic or aneurysmal lesions may require bypass surgery (especially of stenotic cervicobrachial arteries, coronary arteries, or renal arteries); aortic valve replacement (for aortic regurgitation); or percutaneous transluminal angioplasty (especially for stenotic renal arteries causing hypertension).

A review of the experience with vascular interventions in TA supports several general recommendations. First, the mere presence of stenosis does not necessitate intervention. The gut, for example, has such rich collaterals that even critical stenoses of the celiac, superior, or inferior mesenteric arteries usually produce no symptoms and require no surgical intervention. Moreover, many patients with arm claudication will develop collateral circulation and improve substantially over time with medical therapy alone. For upper extremity vascular insufficiency, patiently waiting for a response to medical therapy usually pays higher dividends than undertaking rapid surgical intervention. Second,

whenever possible, surgical intervention should be deferred until TA is in remission; procedures done during active disease often produce disappointing results.[130] Third, bypass surgery yields better results than angioplasty.[118] With bypass graft procedures, autologous vessels give better results than synthetic grafts (restenosis rates of 9% vs. 36%). Patients who undergo aortic surgery are liable to develop anastomotic aneurysms; such aneurysms developed in nearly 14% of patients followed for 20 years.[128,131] Although angioplasty gives good short-term results, long-term results are often disappointing except for very short stenotic segments.[131] The experience with conventional stents has been mostly disappointing.

## Outcome

Twenty percent of TA patients have a self-limited disease. The rest have a relapsing-remitting or progressive course requiring chronic corticosteroid and/or immunosuppressive therapy. Nearly two-thirds of patients experience new angiographic lesions. In one study from the National Institutes of Health, 74% of patients experienced some form of morbidity and 47% were permanently disabled.[104] In a Japanese study of 120 patients, survival at 15 years was 83%.[131] A study of 126 TA patients in the United States reported 10 year survival of 97% and 15 year survival of 85%.[119] Patients with TA do have a higher mortality than the general population; the study estimated the standardized mortality ratio in TA to be 3.0 (95% CI, 1.0 to 8.0).[119] Age of onset older than 35 years; development of major complications (i.e., retinopathy, hypertension, aortic regurgitation, and aneurysm); or a progressive course was associated with decreased survival.[131] Congestive heart failure and renal failure are the most common causes of death.[128] Pregnancy appears to be relatively well tolerated in the presence of good medical care and in the absence of abdominal aortic involvement.[104,132,133]

CHAPTER 89

# Anti-neutrophil Cytoplasmic Antibody–Associated Vasculitis

Sharon Chung • Paul A. Monach

**KEY POINTS**

- The anti-neutrophil cytoplasmic antibody (ANCA)-associated vasculitides are granulomatosis with polyangiitis (GPA), microscopic polyangiitis (MPA), and eosinophilic granulomatosis with polyangiitis (EGPA). They affect small- and medium-sized vessels and share clinical, pathologic, and diagnostic features.
- ANCA testing by immunofluorescence and especially enzyme-linked immunoassay is useful to diagnose ANCA-associated vasculitides in the appropriate clinical context, but its utility in assessing disease activity is unclear.
- GPA is characterized histologically by necrotizing granulomatous inflammation. Common clinical manifestations include destructive sinonasal lesions, pulmonary nodules, and pauci-immune glomerulonephritis. GPA is most commonly associated with cytoplasmic-staining ANCA and antibodies to proteinase 3.
- MPA is characterized histologically by vasculitis without granulomatous inflammation. Common clinical manifestations include rapidly progressive pauci-immune glomerulonephritis and alveolar hemorrhage. MPA is most commonly associated with perinuclear staining ANCA and antibodies to myeloperoxidase.
- EGPA is characterized histologically by eosinophilic tissue infiltration. Common clinical manifestations include asthma and peripheral eosinophilia. Most patients do not produce detectable ANCA.
- For patients with life-threatening disease, combination therapy (with steroids and either cyclophosphamide or rituximab) is needed to induce remission. Remission can be maintained with less toxic medications such as methotrexate and azathioprine. With current treatment regimens, disease remission is achieved in 75% to 93% of patients.

The anti-neutrophil cytoplasmic antibody (ANCA)-associated vasculitides target small- to medium-sized vessels in multiple organ systems, with sinonasal, pulmonary, and renal involvement being particularly common. Specific diseases included in this category are granulomatosis with polyangiitis (GPA), microscopic polyangiitis (MPA), eosinophilic granulomatosis with polyangiitis (EGPA; also known as Churg-Strauss syndrome), and renal limited vasculitis. These diseases are categorized together, given their association with antibodies directed against antigens in the cytoplasm of neutrophils—proteinase 3 (PR3) and myeloperoxidase (MPO)—and many overlapping clinical manifestations, diagnostic testing, and treatment strategies.

## CLASSIFICATION CRITERIA AND NOMENCLATURE

To help clarify and differentiate the various vasculitic syndromes, classification criteria and disease definitions have been proposed by the American College of Rheumatology (ACR) and other groups. In 1990, the ACR proposed classification criteria for both GPA and EGPA. Of note, criteria for MPA were not developed at that time. In essence, these criteria were developed to facilitate research by ensuring that the same types of patients with vasculitis were being enrolled for studies across different institutions and groups.[1]

The classification criteria for GPA were developed by comparing 85 patients who had GPA with 722 patients who had other forms of vasculitis. Four criteria were selected:

1. Abnormal urinary sediment (red blood cell casts or >5 red blood cells/high-power field)
2. Abnormal findings on a chest radiograph (e.g., nodules, cavities, or fixed infiltrates)
3. Oral ulcers or nasal discharge
4. Biopsy findings of granulomatous inflammation

The presence of two or more of these four criteria was associated with a sensitivity of 88.2% and a specificity of 92.0%.[2] ANCAs were not included in these criteria, given their relatively recent identification and the need to further determine their usefulness at the time of the publication of the criteria.

The classification criteria for EGPA were developed by comparing 20 patients with EGPA with 787 patients who had other forms of vasculitis. Six criteria were selected:

1. Asthma
2. Eosinophilia greater than 10% on white blood cell count differential
3. Mononeuropathy (including multiplex) or polyneuropathy
4. Nonfixed pulmonary infiltrates on a chest radiograph
5. Paranasal sinus abnormality
6. A biopsy specimen containing a blood vessel with extravascular eosinophils

The presence of four or more of these six criteria was associated with a sensitivity of 85% and a specificity of 99.7%.[3]

To better define the nomenclature of the systemic vasculitides, the Chapel Hill Consensus Conference (CHCC) was convened in 1994 to reach consensus on the names for the most common forms of systemic vasculitis. Vasculitides were categorized into large-, medium-, and small-vessel

groups. Of note, this conference formally defined MPA for the first time and differentiated this entity from classic polyarteritis nodosa (PAN) by defining MPA as a pauci-immune necrotizing vasculitis affecting small vessels, with or without medium-vessel involvement. PAN was defined as an arteritis of medium-sized and small vessels without involvement of the arterioles, venules, or capillaries (including glomerular capillaries).[4] The CHCC nomenclature system was reviewed in 2012 and recommended a shift from using eponyms to noneponymous replacements. Other changes include the addition of variable vessel and single-organ vasculitis, as well as vasculitis associated with systemic disease and vasculitis associated with probable etiology.[5] The names and definitions of ANCA-associated vasculitis—GPA, MPA, and EGPA, as set forth by the CHCC 2012 conference—are presented in Table 89-1. The definitions for other small-vessel vasculitides are included for comparison.

It is important to note that the ACR classification criteria and CHCC definitions are not intended to serve as diagnostic criteria. In a prospective study, the ACR classification criteria were found to perform poorly as diagnostic criteria for GPA, PAN, giant cell arteritis, and hypersensitivity vasculitis. Vasculitis was diagnosed in 51 of 198 patients (26%). The positive predictive value for the criteria for these four vasculitides ranged from 17% to 29% for all patients and 29% to 75% of patients with vasculitis.[6] In a study of GPA, EGPA, PAN, and MPA using diagnostic criteria based on the CHCC definitions, many cases fulfilled more than one set of criteria, and few patients fulfilled the MPA criteria.[7] Other groups have developed diagnostic criteria for ANCA-associated vasculitides, but these criteria are not widely accepted.[8] ACR and European League against Rheumatism (EULAR) are currently developing diagnostic criteria and updating classification criteria in their jointly sponsored Diagnostic and Classification Criteria in Vasculitis study.

## EPIDEMIOLOGY

Epidemiologic studies of the ANCA-associated vasculitides (AAV) have been hampered by the evolving classification criteria and disease definitions, along with the rarity of these diseases. Most epidemiologic investigations of AAV have studied populations of European descent. These studies suggest an overall incidence of 10 to 20 individuals per million per year, with a slight male predominance (male to female, 1.5:1). These diseases are rare in childhood and the incidence increases with age, with the peak incidence occurring in persons between 65 and 74 years of age (6 cases/100,000).[9] Compared with patients who experience the development of AAV as adults, patients with childhood-onset AAV have a higher incidence of subglottic stenosis and a lower incidence of renal involvement.[10]

**TABLE 89-1** Names and Definitions of Small Vessel Vasculitides as Presented by the 2012 Chapel Hill Consensus Conference

| Name | Definition and Comments |
|---|---|
| Small-vessel vasculitis | Vasculitis predominantly affecting small vessels, defined as small intraparenchymal arteries, arterioles, capillaries, and venules. Medium-sized arteries and veins may be affected. |
| ANCA-associated vasculitis | Necrotizing vasculitis with few or no immune deposits predominantly affecting small vessels (i.e., capillaries, venules, arterioles, and small arteries), associated with MPO ANCA or PR3 ANCA. Not all patients have ANCA. Add a prefix indicating ANCA reactivity (e.g., MPO-ANCA, PR3-ANCA, ANCA-negative). |
| Granulomatosis with polyangiitis | Necrotizing granulomatous inflammation usually involving the upper and lower respiratory tract, and necrotizing vasculitis affecting predominantly small- to medium-sized vessels (e.g., capillaries, venules, arterioles, arteries and veins). Necrotizing glomerulonephritis is common. |
| Microscopic polyangiitis | Necrotizing vasculitis with few or no immune deposits predominantly affecting small vessels (i.e., capillaries, venules, or arterioles). Necrotizing arteritis involving small- and medium-sized arteries may be present. Necrotizing glomerulonephritis is very common. Pulmonary capillaritis often occurs. Granulomatous inflammation is absent. |
| Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome) | Eosinophil-rich and necrotizing granulomatous inflammation often involving the respiratory tract, and necrotizing vasculitis predominantly affecting small- to medium-sized vessels, and associated with asthma and eosinophilia. ANCA is more frequent when glomerulonephritis is present. |
| Immune complex vasculitis | Vasculitis with moderate to marked vessel wall deposits of Ig and/or complement components predominantly affecting small vessels (i.e., capillaries, venules, arterioles, and small arteries). Glomerulonephritis is frequent. |
| Anti-glomerular basement membrane disease | Vasculitis affecting glomerular capillaries, pulmonary capillaries, or both, with GBM deposition of anti-GBM autoantibodies. Lung involvement causes pulmonary hemorrhage, and renal involvement causes glomerulonephritis with necrosis and crescents. |
| Cryoglobulinemic vasculitis | Vasculitis with cryoglobulin immune deposits affecting small vessels (predominantly capillaries, venules, or arterioles) and associated with serum cryoglobulins. Skin, glomeruli, and peripheral nerves are often involved. |
| IgA vasculitis (Henoch-Schönlein purpura) | Vasculitis, with IgA1-dominant immune deposits, affecting small vessels (predominantly capillaries, venules, or arterioles). Often involves skin and gastrointestinal tract, and frequently causes arthritis. Glomerulonephritis indistinguishable from IgA nephropathy may occur. |
| Hypocomplementemic urticarial vasculitis (anti-C1q vasculitis) | Vasculitis accompanied by urticaria and hypocomplementemia affecting small vessels (i.e., capillaries, venules, or arterioles), and associated with anti-C1q antibodies. Glomerulonephritis, arthritis, obstructive pulmonary disease, and ocular inflammation are common. |

ANCA, Anti-neutrophil cytoplasmic antibody; GBM, glomerular basement membrane; MPO, myeloperoxidase; PR3, proteinase 3.

AAVs appear to be more common in populations of European descent. In France, the overall prevalence of GPA, MPA, PAN, and EGPA was 2.0 times higher for subjects of European ancestry (104.7 cases/million) than for non-Europeans (52.5 cases/million).[11] GPA and MPA are rarely seen in persons of African descent.[12] Additional study is needed regarding the epidemiology of AAV in non-European populations.

Studies have also shown an increase in prevalence since the 1990s. Between 1994 and 2006 in Germany, the prevalence of GPA increased from 58 to 98 cases per million, MPA increased from 9 to 28 cases per million, and EGPA increased from 7 to 24 cases per million.[13] In the United Kingdom (UK), the prevalence of GPA increased from 28.8 per million in 1990 to 64.8 per million in 2005.[14] The increase in prevalence likely reflects increased awareness and diagnosis of the diseases after the development of the ACR classification criteria and CHCC definitions and ANCA testing, as well as improved survival.

In European populations, GPA is the most prevalent AAV. The incidence of GPA ranges from 4.9 to 10.5 cases per million per year, with a higher incidence in northern Europe than in southern Europe (e.g., an incidence of 10.5/million/year in Norway and 4.9/million/year in Spain). The overall prevalence ranges from 24 to 157 per million, with the highest prevalences reported in Sweden and the UK.[9,13] Variation in incidence and prevalence between countries has suggested that disease risk declines in a north-south gradient in the Northern Hemisphere.[14]

The incidence of MPA among European populations ranges from 0.5 to 11.6 cases/million/year. Unlike GPA, the highest incidence of MPA seems to occur in Southern Europe, specifically in Greece and Spain. MPA is also more common in non-European populations, with an incidence of 14.8 cases/million/year in Japan and 24.0 cases/million/year in Kuwait, the highest reported incidence thus far.[9,14] The prevalence of MPA ranges from 0 to 66 cases per million among European countries.[9]

Studies in Japan have shown the reverse in prevalence and incidence for the AAV compared with the UK. The overall prevalence and incidence of AAV appears to be similar between Japan (prevalence, 86 cases per million; incidence, 22.6 cases per million) and the UK (prevalence, 50 cases per million; incidence, 21.8 cases per million). However, more than 80% of patients in Japan are perinuclear-staining (p-ANCA) or MPO positive, whereas two thirds of patients in the UK are cytoplasmic-staining (c-ANCA) or PR3 positive. As suggested from the serologic differences, MPA is more common in Japan (occurring in 83% of patients with AAV), whereas GPA is more common in the UK (occurring in 66% of patients with AAV). Compared with patients in the UK who have GPA, renal involvement is less common in Japan.[15,16] In a study of systemic vasculitis in China, MPA was also more common than GPA (3:1), and 75% of patients were p-ANCA positive, whereas 13% were c-ANCA positive.[17] These findings suggest that granulomatosis in this family of diseases is less common in Asian populations.

EGPA is the least prevalent of the ANCA-associated vasculitides. Among European populations, the incidence of EGPA ranges from 0.5 to 6.8 cases per million individuals.[9,14,18] The incidence of EGPA among patients with asthma ranges from 34.6 to 64.4 per million.[18,19] The overall prevalence of EGPA in European populations has been estimated to range from 2 to 38 cases per million.[9,11] A gender predominance has not been clearly demonstrated. In Japan, the prevalence of EGPA has been estimated to be 17.8 cases per million, with women more frequently affected than men.[20]

### Triggering Factors

Environmental exposures, infections, and drugs have been hypothesized to be triggering factors for the development of AAV. Among environmental and occupational exposures, the most consistent associations have been observed with crystalline silica, with most studies showing an odds ratio (OR) of 2.5 to 5. Associations with other exposures such as heavy metals, farming, organic solvents, and pesticides have been studied, but results have not been consistent.[21] The influence of infection on GPA pathogenesis has been suggested by a cyclical pattern of occurrence observed in some studies.[22] However, the only clear association is seen with *Staphylococcus aureus*, where nasal carriage of *S. aureus* is associated with an increased risk of relapse in GPA.[23] The role of *S. aureus* or other infectious agents in disease initiation has not been established. Lastly, the most commonly reported drugs causing AAV include hydralazine, minocycline, propylthiouracil, and levamisole-adulterated cocaine.[24] Use of leukotriene antagonists and omalizumab has been linked to the development of EGPA. These agents may not be directly causative but instead unmask underlying EGPA by allowing corticosteroid tapering or are prescribed to patients with undiagnosed and worsening EGPA. However, a direct causal link cannot be excluded.[25-27]

## GENETICS

GPA, MPA, and EGPA are complex genetic diseases—instead of a single gene variant causing disease, multiple genetic variants, each with potentially modest effect(s), influence disease risk. Thus large cohorts of patients and control subjects are needed to identify genetic risk factors. Family-based, candidate gene, and genome-wide studies have been conducted to identify genetic susceptibility loci for the AAV. GPA is the most thoroughly studied of these three diseases.

Familial studies of GPA have suggested a genetic influence on disease susceptibility. A nationwide registry–based study in Sweden showed that the relative risk of GPA in a first-degree relative of a person with GPA was estimated to be 1.56 (95% CI, 0.35 to 6.9). This familial risk is lower than in other autoimmune diseases such as systemic lupus erythematosus and multiple sclerosis but is of similar magnitude as the familial risk in rheumatoid arthritis.[28] First-degree relatives of patients with GPA have an increased incidence of seropositive rheumatoid arthritis (hazard ratio [HR], 1.54; 95% confidence interval [CI], 1.09 to 2.19), as well as other autoimmune diseases, including multiple sclerosis (HR, 1.92; 95% CI, 1.16 to 3.16).[29] Children of persons with GPA have an increased risk of rheumatoid arthritis (standardized incidence ratio, 1.34).[30] In an independent cohort, a genetic risk score based on rheumatoid arthritis

susceptibility genes was associated with GPA risk.[31] These findings suggest that GPA and rheumatoid arthritis share genetic risk factors.

Candidate gene studies of GPA have replicated associations with the class II human leukocyte antigen (HLA) region, *CTLA4*, *PTPN22*, and *SERPINA1*. Although genetic studies of the HLA can be difficult to interpret given the polymorphic nature of the genes and the extensive linkage disequilibrium in the area, associations between GPA and the extended haplotype containing *HLA-DPB1*0401* have been observed and replicated in ANCA-positive patients.[32,33] *Cytotoxic T-lymphocyte–associated antigen 4* (*CTLA4*) is found on T cells and inhibits T cell function. Multiple variants of *CTLA4* have been shown to confer genetic risk for GPA, with some variants affecting surface expression or messenger RNA stability.[31,34-36] *PTPN22* codes for Lyp, a tyrosine phosphatase that acts with c-src tyrosine kinase as a critical negative regulator of T cell receptor signaling. The R620W (rs2476601) variant is associated with GPA[31,37,38] and interrupts its binding with c-src tyrosine kinase, thus altering B and T cell receptor responsiveness. *SERPINA1* codes for α1 antitrypsin, a serine protease inhibitor that is a major inhibitor of PR3. The rare Z and S alleles of *SERPINA1*, which lead to a deficiency of the enzyme, have been associated with GPA.[39] Genetic variation in the HLA region, *CTLA4*, and *PTPN22* has been associated with multiple autoimmune diseases, including systemic lupus erythematosus and rheumatoid arthritis.

The first genome-wide association study of GPA and MPA, published in 2012, examined a total of 2267 persons with AAV and 6858 control subjects, all of Northern European descent. The most statistically significant genetic associations in the combined (GPA and MPA) cohort were observed with *HLA-DP* (OR, 3.67; $P = 1.5 \times 10^{-71}$), *COL11A2* (OR, 1.51; $P = 7.8 \times 10^{-15}$), and *SERPINA1* (OR, 0.51; $P = 2.4 \times 10^{-9}$). However, associations based on ANCA specificity were stronger than associations with specific disease phenotypes or the overall cohort. For example, the *HLA-DP* association was strongest in anti–PR3-positive individuals (OR, 7.03; $P = 6.2 \times 10^{-89}$). Associations with *SERPINA1* were observed in anti-PR3 individuals (OR, 0.53; $P = 5.6 \times 10^{-12}$) and not in anti–MPO-positive individuals (OR, 1.1; $P = 2.2 \times 10^{-1}$). Associations with the PR3 gene were only observed in anti–PR3-positive individuals (OR, 0.73; $P = 2.6 \times 10^{-7}$). In the anti–MPO-positive subgroup, *HLA-DQ* showed stronger associations (OR, 0.65; $P = 2.1 \times 10^{-8}$).[40] These findings suggest that genetic variation may influence autoantibody specificity more strongly than clinical disease phenotype.

A second genome-wide association study focused specifically on GPA studied a total of 1020 GPA cases and 2734 control subjects who were all of European descent. This study confirmed the strong association with *HLA-DP* and found that the *HLA-DPB1*04* allele fully accounted for the association. In addition, an independent association with the *SEMA6A* (OR, 0.74; $P = 2.09 \times 10^{-8}$) was observed in the combined cohort[41] but could not be replicated by a second group.[42] A nominal association was also observed with *SERPINA1*.

A genome-wide association study of EGPA has not been published. Candidate gene studies have implicated *HLA-DRB1*0401* and the extended *IL-10.2* haplotype as genetic susceptibility loci for EGPA.[43-45]

The genetic association studies conducted thus far have primarily examined persons of European descent, and the epidemiology of GPA and MPA differs between European and Asian countries. Genetic studies of MPA in Japan have suggested associations between MPA and *IRF5*, the *HLA-DRB1*09:01-DQB1*03:03* haplotype, and *KIR2DS3*,[46,47] but these findings need to be replicated. A study of African Americans with AAV showed that the odds of having *HLA-DRB1*15* were 73.3-fold higher in PR3-ANCA–positive persons compared with healthy control subjects. In addition, a disproportionate number of persons carried the *HLA-DRB1*1501* allele of European descent compared with the *HLA-DRB1*1503* allele of African descent.[12] Further studies in non-European populations are needed to determine whether the genetic risk factors identified in European persons are broadly applicable to other ethnic groups.

## CLINICAL MANIFESTATIONS

Although the AAV can affect almost all organ systems, the frequency of organ system involvement varies greatly. Data on organ system involvement come from a small number of cohorts of 30 to 400 patients.[48-59] Some reports indicate that new organ system involvement occurs frequently over time, particularly in GPA.[48,49] The diversity of presentations within a given organ system is apparent from case series and reviews focused on that organ system and reports of particularly unusual cases.[46,49,58-61]

Not all clinical features of AAV are directly attributable to local vascular damage. This phenomenon is obvious with regard to constitutional symptoms, but in addition, the risk of venous thromboembolic events is elevated in the absence of inflammation in veins,[60,61] and the pathophysiology of arthritis is unknown. Also, the extent to which myalgia and gastrointestinal (GI) symptoms indicate vasculitis in these organ systems is not known.

As a rough approximation, the features of MPA can all be seen in GPA or EGPA, particularly in ANCA-positive patients. GPA, by definition, features perivascular necrotizing granulomatous inflammation, and EGPA features eosinophil-rich granulomatous inflammation and/or parenchymal infiltration by eosinophils, leading to greater diversity of clinical phenotypes. Unfortunately, many of the largest series and clinical trials do not allow comparison of organ system involvement in MPA, GPA, and EGPA, because either the first two or all three entities were pooled as ANCA-associated vasculitis.[56,62-65]

### Granulomatosis with Polyangiitis

Although the range of presentations and subsequent courses in GPA is extraordinarily broad, longitudinal analyses of larger cohorts generally agree on the frequency of involvement of different organ systems over time (Table 89-2).[48,49,51] Frequencies in children appear to be similar to those in adults.[50] Inflammation in the upper airway is the most common initial symptom.[48,49] Progression to systemic vasculitis, particularly with glomerulonephritis or alveolar hemorrhage, remains a common route to diagnosis, but the

**TABLE 89-2** Manifestations Over Time in the Subtypes of ANCA-Associated Vasculitis in the Largest Published Series*

| Organ System | GPA | MPA | EGPA |
|---|---|---|---|
| ENT | 83-99 | 1-20 | 48-77 |
| Joint/muscle | 59-77 | 14-54+ | 30-39+ |
| Kidney | 66-77 | 69-100 | 22-27 |
| Lung | 66-85 | 25-55 | 51-58 |
| Eye | 34-61 | 1-15 | 7 |
| Heart | 8-25 | 3-24 | 16-27 |
| Skin | 33-46 | 11-62 | 40-57 |
| Peripheral nerve | 15-40 | 13-60 | 51-76 |
| CNS | 8-11 | 5-12 | 5-14 |
| GI tract | 6-13 | 3-31 | 22-31 |
| Constitutional symptoms | 58+ | 67-84 | 49-68 |

*Numbers indicate percentages. Not all manifestations were reported in all studies. Some studies reported separate individual manifestations that were pooled into groups for this table; in such cases, the highest percentage among those separate manifestations was used, and "+" indicates that the percentage for the groups of pooled manifestations is likely to be higher.

EGPA, Eosinophilic granulomatosis with polyangiitis; ENT, ear, nose, and throat; GI, gastrointestinal; GPA, granulomatosis with polyangiitis; MPA, microscopic polyangiitis.

development of ANCA testing has facilitated diagnosis at more "localized"[66,67] or "limited"[68] stages or with unusual presentations. Constitutional symptoms and inflammation in the upper and/or lower airway may develop simultaneously with systemic vasculitis or may precede it by weeks, months, or years.[67]

Frequent epistaxis and mucopurulent nasal discharge are common. The patient and subsequently the physician are often alerted to the severity of inflammation in the nasal cavity by the presence of pain and hard crusts overlying actively inflamed or eroded tissue and exacerbated by poor air flow. Inflammation of the paranasal sinuses causing pain (Figure 89-1) is also common. Ear congestion and conductive hearing loss can result from inflammation of the middle ear or the auditory tube or by obstruction of the tube at its entry into the nose. Inflammation of the subglottic trachea occurs in approximately 15%,[48,69,70] particularly in children and young adults.[71] Oral ulcers, gingivitis, and auricular chondritis are well-described but less frequent manifestations.[48,69,70,72]

Upper airway inflammation in GPA is notable for its destructive potential, but permanent damage does not always occur and is highly variable in its pace. The nasal septum is particularly at risk, and septal perforation can progress to collapse and a characteristic "saddle-nose" deformity (Figure 89-2). Bone erosion occurs elsewhere—for example, in the sinuses, hard palate, and orbit—but is much less common. Subglottic involvement often causes obstruction (Figure 89-3) as a consequence of either active inflammation or subsequent scarring and can be life-threatening.[71]

Eye and orbital involvement is also striking in GPA, both in terms of frequency (30% to 60% over time and much higher than in MPA or EGPA) and diversity.[48,51,73] Conjunctivitis and episcleritis are the most common forms and pose no danger to the patient. In contrast, scleritis can threaten vision if it is not treated aggressively. Scleritis is usually painful, whereas conjunctivitis and episcleritis are not painful, but absence of pain does not rule out scleritis, and these conditions cannot be distinguished by simple inspection. Retinal vasculitis, uveitis, oculomotor nerve

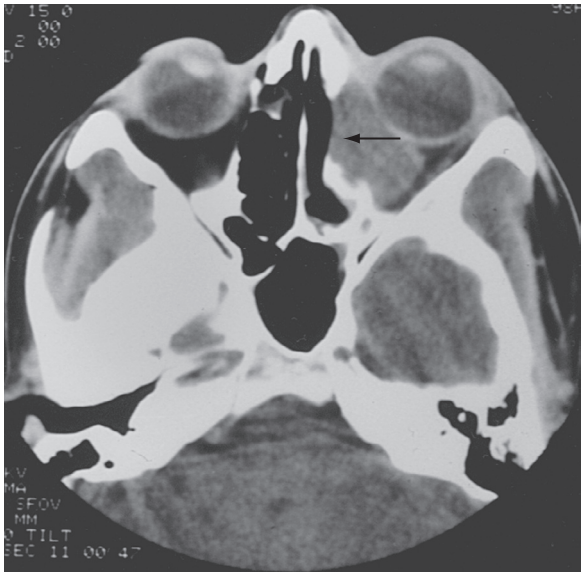

**Figure 89-4** Computed tomography scan of the orbits, showing a retro-orbital mass (orbital pseudotumor).

palsy, and optic neuropathy are less common but well described.[51,73] Inflammation of the lacrimal gland, sac, and/or duct, seen in about 10% of patients, leads to excessive tearing, and blockage of the lacrimal duct's entry into the nose can produce similar symptoms.[48,73] Orbital pseudotumor (Figure 89-4) is notable because it is both relatively common (6% to 15%) and dangerous, with risk of blindness reported at 50% despite aggressive treatment.[48,51,73]

The lung is affected in several distinct ways. Pulmonary nodules, which are necrotizing and therefore frequently cavitate (Figure 89-5), often occur prior to or in the absence of systemic vasculitis and thus are a common feature of "localized"[66,67] or "limited"[68] GPA. Nodular disease is often asymptomatic or merely produces cough. Alveolar hemorrhage, characterized by dyspnea and hemoptysis that can vary from mild to life-threatening, is also common but is distinct from nodular disease clinically and radiographically. However, dichotomizing lung disease in GPA into nodular or hemorrhagic forms understates the wide range of inflammatory disease that has been observed.[74,75] Apart from the lung parenchyma, pleuritis[48] and endobronchial lesions distal to the subglottis[76] are well described; the frequency of the latter may be underestimated because they can only be definitively diagnosed by bronchoscopy. Although clinically significant pulmonary fibrosis and bronchiectasis occur in GPA, their frequency is less than one might expect, considering how common parenchymal lung disease is; most lesions heal without scarring.

Musculoskeletal pain is common even in the early phases of disease and therefore can offer the rheumatologist the opportunity to diagnose and intervene in GPA before permanent organ damage occurs. Unfortunately, the presentations are variable and nonspecific. Monoarticular, oligoarticular, and polyarticular involvement are all seen. Arthralgia is more common than inflammatory arthritis that can be detected on physical examination.[48] Myalgia is usually not accompanied by abnormalities on examination or laboratory testing, and thus the musculoskeletal features of GPA can resemble polymyalgia rheumatica, spondyloarthropathies, rheumatoid arthritis, crystal arthropathies, the full range of connective tissue diseases, or even fibromyalgia. One distinctive articular presentation is worth emphasizing because it is relatively common in GPA but uncommon in other diseases: migratory arthralgias or arthritis of large joints, in which patients experience severe pain in a wrist, elbow, shoulder, ankle, or knee for a few days before complete resolution, to be followed soon afterward by similar symptoms in one to two other joints.

Cutaneous involvement in GPA includes the full range of presentations of cutaneous small-vessel vasculitis and, less commonly, vasculitis of small arteries. Thus purpura, papules, vesicles/bullae, ulcers, digit ischemia, subcutaneous nodules, and livedo racemosa have all been reported.[77,78] A characteristic lesion is a superficial, nonerythematous cutaneous nodule with pathologic findings showing a necrotizing, palisading granuloma, but this lesion is also seen in EGPA and other systemic diseases.[79,80]

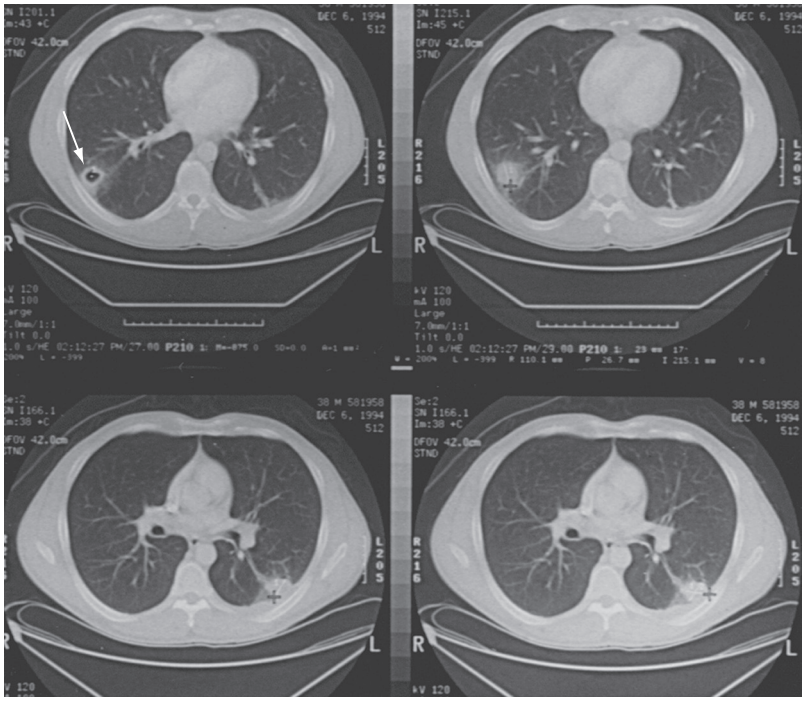

**Figure 89-5** Computed tomography of the lungs, showing pulmonary nodules. The right-sided nodule is cavitary *(arrow)*.

Peripheral neuropathy can present either as a sensory polyneuropathy or a mononeuritis multiplex with both sensory and motor deficits. Neuropathic pain is common but not universal in the setting of sensory loss. Cranial neuropathies are less frequent, with the exception of sensorineural hearing loss, the pathophysiology of which is unclear and which is an important source of morbidity.[81] Although CNS abnormalities such as strokes occur in patients with GPA, vasculitis of intracerebral arteries is thought to be rare; pachymeningitis is another well-described but uncommon manifestation.[82]

As with the CNS, patients with GPA will have cardiac problems and GI symptoms, but vasculitis of the heart muscle or the GI organs is very uncommon.[83,84] Pericarditis, in contrast, is a more common source of chest pain that is directly attributable to GPA.[48]

Glomerulonephritis (GN) is apparent in many patients at diagnosis and in more than half at some point during the course of disease.[48,49,51] On biopsy, the GN is characterized as pauci-immune and is frequently necrotizing and crescentic (Figure 89-6). The rate of progression is highly variable: renal function may deteriorate significantly within a week or slowly over months or even years. Because renal disease seldom produces gross hematuria, it is only apparent to the patient in the setting of uremia or nephrotic syndrome, and the latter occurs in a minority of patients.

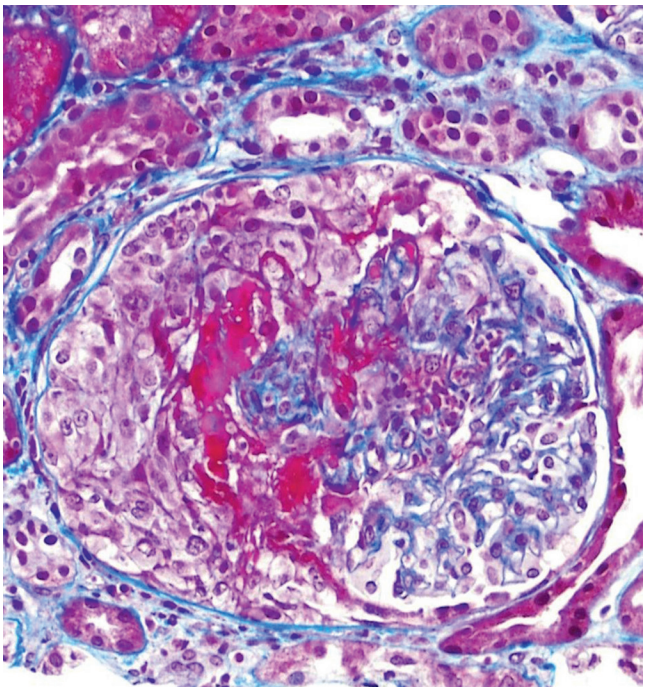

**Figure 89-6** Anti-neutrophil cytoplasmic antibody–associated crescentic glomerulonephritis. This Periodic acid–Schiff–stained section demonstrates a glomerulus with a cellular crescent partially obliterating Bowman's space. Because all types of crescentic glomerulonephritis appear similar by light microscopy, immunofluorescence is needed to distinguish among pauci-immune, immune complex, and anti–glomerular basement membrane antibody-mediated etiologies. *(Courtesy Dr. S. Bagnasco.)*

## Microscopic Polyangiitis

The clinical features of MPA consist of a limited subset of those seen in GPA (i.e., features that lack granulomatous inflammation). Large series published recently have made important contributions to the literature.[51,59] Reported frequencies of manifestations have varied much more than in GPA or EGPA (Table 89-2), likely for multiple reasons:

series from nephrology centers are expected to report very high rates of renal involvement[53]; series that include ANCA-negative patients without GN may include patients in whom the diagnosis might be debated[51,52]; confidence in defining involvement in some organ systems (e.g., cardiac, GI, and CNS) is challenging; and most interestingly, there appear to be important differences in MPA between patients in Europe and East Asia, particularly in the type of lung involvement.[59]

With those caveats, the following tentative statements can be made: GN is probably more common in MPA than in GPA, at least at diagnosis.[48,49,51,53,59,85] Cutaneous vasculitis, neuropathy,[86] constitutional and musculoskeletal symptoms, and risk of alveolar hemorrhage are probably similar. Involvement of the eye is distinctly less common. GI involvement has been reported at relatively high frequencies in some series (based on symptoms) and low frequencies in others, so it is difficult to draw conclusions.[51,59] As with GPA, it is also difficult to determine the rate of true CNS or myocardial vasculitis; subclinical myocardial abnormalities have been detected.[87] One manifestation that appears to be more common in MPA than GPA is pulmonary fibrosis, particularly but not exclusively in series from Japan and China.[59,88-90]

The duration of symptoms prior to diagnosis of MPA is wide, and the initial symptoms are often nonspecific constitutional and musculoskeletal complaints. Although symptoms commonly develop over days to months, many cases have been reported in which nonspecific symptoms had been present for years.[91] Patients who have MPA (or anti-MPO antibodies) typically present at a more advanced stage of renal failure than do patients with GPA (or anti-PR3 antibodies),[92] and histologically, renal damage at presentation is worse, on average, in patients with MPA/anti-MPO than in patients with GPA/anti-PR3.[93] However, it is not clear that GN in MPA is intrinsically worse than in GPA; alternatively, the "granulomatous" manifestations of GPA may lead to earlier diagnosis. Severe pauci-immune GN associated with anti-MPO antibodies and without any evidence of vasculitis elsewhere is well known to nephrologists and is often referred to as renal-limited vasculitis or necrotizing crescentic GN rather than MPA.[53,62]

### Eosinophilic Granulomatosis with Polyangiitis (Churg-Strauss Syndrome)

The hallmarks of EGPA are asthma and peripheral eosinophilia out of proportion to what might be seen in asthma or allergic diseases, but other symptoms and findings are needed to make the diagnosis.[94] As with MPA and GPA, constitutional and musculoskeletal symptoms are common and may be the first clue to the presence of disease beyond asthma. Asthma itself is almost universal, often but not always severe, and highly variable in its onset relative to the onset of EGPA. Although EGPA is intimately linked to asthma, the conditions are distinct: patients frequently have asthma exacerbations without evidence of eosinophilic pneumonia or other manifestations of EGPA, and it is often asthma rather than EGPA-specific symptoms that requires control with chronic use of corticosteroids.[54,94]

The organ-specific manifestations of EGPA are attributable to vasculitis, parenchymal eosinophilic infiltration, or both. Reported frequencies of organ involvement are shown in Table 89-2.[54,57,58] Several comparisons to GPA and MPA are informative. Upper airway involvement is common in EGPA, but in contrast to GPA, it is usually "allergic" in character and is seldom destructive. GN and alveolar hemorrhage are uncommon and are highly associated with positive ANCA (usually anti-MPO),[54,58,95] which is detected in only 35% to 40% of patients with EGPA overall.[58,95]

Skin involvement is at least as common in EGPA as in GPA but again includes "allergic" lesions such as urticaria in addition to a wide range of presentations of cutaneous vasculitis.[77] Nodules representing necrotizing granulomas can be seen, as in GPA. The rate of GI disease is difficult to discern from series relying on symptoms, but because eosinophilic infiltration of the GI tract is well described in other settings,[96] it would not be surprising for GI disease to be more common in EGPA than in GPA or MPA.

Neuropathy, which is thought to be due to vasculitis rather than the neurotoxins of eosinophils, is more common in EGPA than in GPA or MPA,[51,54,57] and mononeuritis multiplex is frequently a useful feature in distinguishing EGPA from a hypereosinophilic syndrome (HES).[58,97] Finally, clinically important cardiac involvement is clearly a greater risk in EGPA than in MPA or GPA, with about 15% of patients having eosinophilic myocarditis severe enough to cause cardiomyopathy.[51,54] Cardiac disease resembles that seen in HES and is usually seen in ANCA-negative patients,[54,58,95] another example of the frequent separation of eosinophilic and vasculitic manifestations in EGPA.

## DIAGNOSTIC TESTING

The roles of laboratory tests, other diagnostic tests, and biopsy in diagnosing GPA, MPA, or EGPA vary with the clinical setting.

ANCAs were initially discovered and established as a clinical test using immunofluorescence staining of neutrophils. Subsequently, the target antigen for the c-ANCA pattern was identified as PR3, and the antigen for the p-ANCA pattern was identified as MPO. Although immunofluorescence staining (Figure 89-7) is often used in addition to, or as a screening test prior to, testing for anti-PR3 and anti-MPO antibodies by enzyme-linked immunosorbent assay, antigen-specific testing is much more valuable. In particular, p-ANCA immunofluorescence has poor specificity for AAV, whereas anti-MPO antibodies have high specificity for AAV.

Antibodies to PR3 or MPO are sufficiently specific that they can be considered diagnostic in cases in which vasculitis is highly likely by other criteria (Table 89-3). Examples of such clinical settings include digital ischemia (diagnosed by physical examination); noncompressive neuropathy (diagnosed by nerve conduction studies); and alveolar hemorrhage (diagnosed by either bronchoalveolar lavage or witnessed hemoptysis plus CT imaging consistent with diffuse bleeding). There is a difference of opinion in one key area. Some experts believe that a kidney biopsy should be performed whenever possible to confirm pauci-immune glomerulonephritis and give prognostic information derived from the degree of permanent damage,[93,98,99] whereas other experts might argue that red blood cell casts in the urine in the setting of anti-PR3 or anti-MPO antibodies is sufficient.

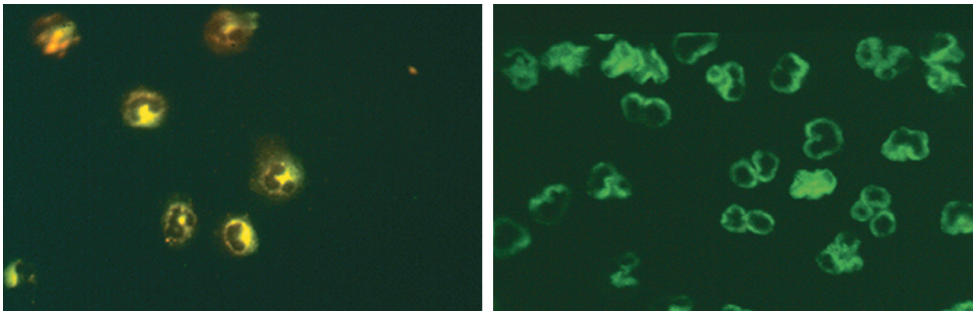

**Figure 89-7** Immunofluorescence of cytoplasmic anti-neutrophil cytoplasmic antibody (c-ANCA, *left*), which is highly correlated with anti-proteinase 3 antibodies, and perinuclear staining (p-ANCA, *right*), which is indicative of anti-myeloperoxidase antibodies. Positive immunofluorescence staining should be confirmed with antigen-specific testing to proteinase 3 and myeloperoxidase. *(Courtesy Dr. C.G.M. Kallenberg.)*

**TABLE 89-3** Clinical Settings in Which It Is Appropriate to Check ANCA and in Which Positive Testing for Anti-proteinase 3 or Anti-myeloperoxidase Antibodies Could Be Considered Diagnostic of GPA or MPA*

| Disease | Manifestation | Examination Technique | Laboratory and Other Testing | Imaging | Problems with Biopsy |
|---|---|---|---|---|---|
| GPA > MPA | Scleritis | Ophthalmologic examination | | | |
| GPA | Orbital pseudotumor | Routine inspection, or with measurement tool | | CT or MRI | |
| GPA > MPA | Sensorineural hearing loss | | Audiography | | Impossible |
| GPA | Sinonasal inflammation | Otoscope or fiberoptic examination | | CT of sinuses | All 3 characteristic features† seen in only 10% of GPA |
| GPA | Subglottic inflammation | Laryngoscopy | | CT of neck | Correlates poorly with examination or outcome |
| GPA | Pulmonary nodule(s) | | | CT of chest | 1. Trans-bronchial: all 3 diagnostic features† are seldom seen<br>2. Surgical biopsy: invasive |
| GPA/MPA | Alveolar hemorrhage | Inspection (witnessed hemoptysis) or bronchoscopy with BAL | | CT of chest | Invasive, and patient is often critically ill |
| GPA/MPA | Digit ischemia | Routine inspection | | Angiography | Impossible |
| GPA/MPA | Peripheral neuropathy | Neurologic examination: sensory and motor | Nerve conduction studies/ electromyography | | Likely to result in an area of permanent sensory deficit; small chance of chronic pain |
| GPA/MPA | Nephritis | | Urine sediment: RBC casts | | |

*If accompanied by marked peripheral eosinophilia, then EGPA would be the most probable diagnosis. Biopsy is often unnecessary to diagnose scleritis or alveolar hemorrhage, is often nonspecific or nondiagnostic for GPA in sinonasal or subglottic or orbital disease, and is impossible in digit ischemia or sensorineural hearing loss. The value of biopsy of a pulmonary nodule or peripheral nerve depends on how typical or atypical the overall presentation is for anti-neutrophil cytoplasmic antibody–associated vasculitides. Some experts recommend a kidney biopsy for all patients with suspected nephritis. Skin disease is not included in the table because the appearances of cutaneous vasculitis are nonspecific; skin biopsy is therefore particularly valuable for diagnosing vasculitis, although differentiation from other causes of cutaneous vasculitis is often impossible.

†Granulomatous inflammation, necrosis, and small-vessel vasculitis.

BAL, Bronchoalveolar lavage; CT, computed tomography; EGPA, eosinophilic granulomatosis with polyangiitis; GPA, granulomatosis with polyangiitis; MPA, microscopic polyangiitis; RBC, red blood cell.

The poor specificity of p-ANCA alone (i.e., without positive testing for antibodies to MPO) is well known. However, positive testing for anti-MPO or anti-PR3 antibodies has been well documented in three conditions other than AAV: endocarditis,[100] systemic lupus,[101] and use of cocaine adulterated with levamisole.[102] These associations are important to remember because the clinical syndromes overlap substantially with those of AAV. In all of these entities, the presence of additional autoantibodies is the rule. In the case of cocaine/levamisole, there is often a disconnect between the observed ANCA pattern by immunofluorescence and testing for the specific antigen.[102]

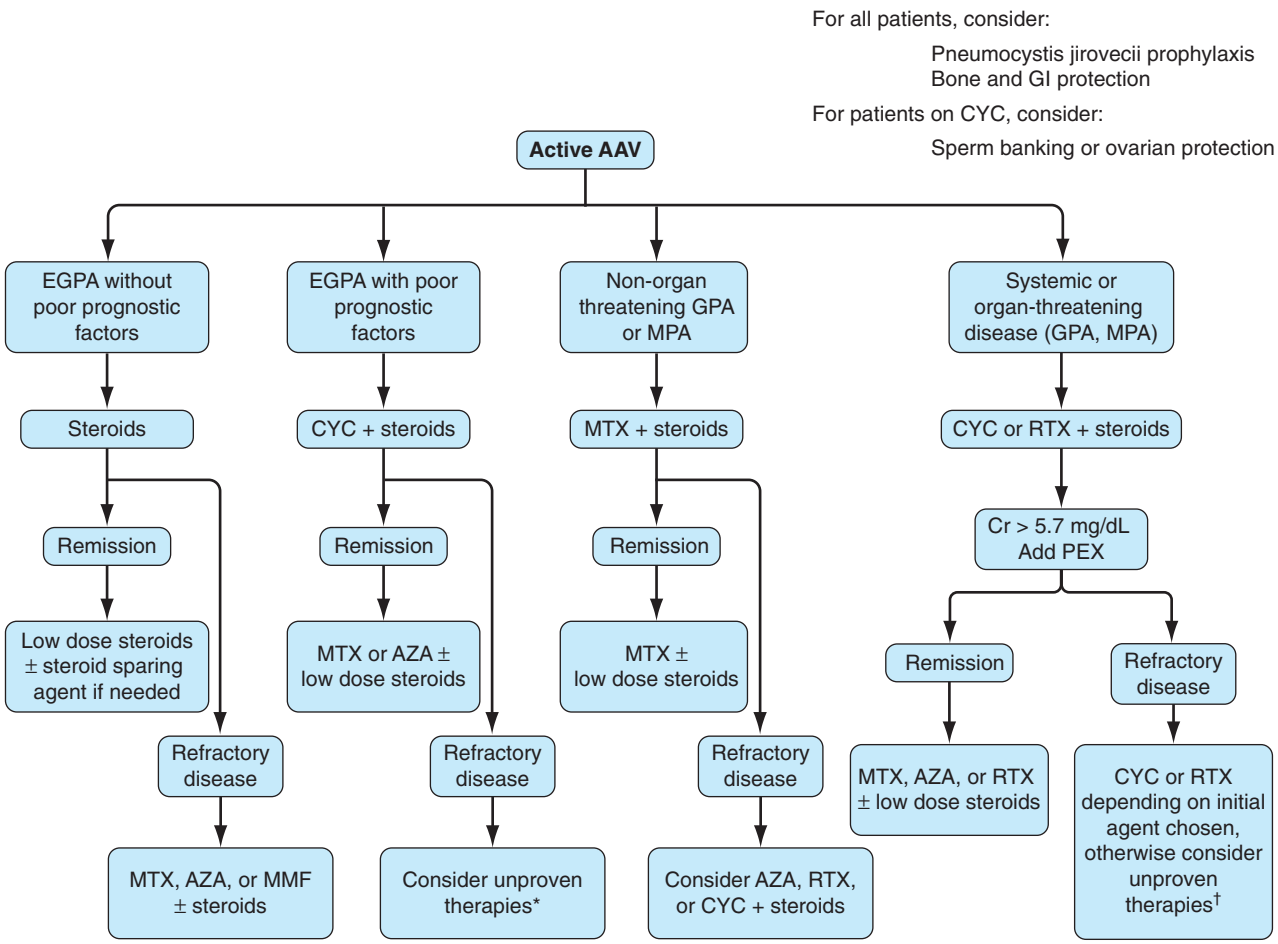
Other than the characteristic disease in the kidney (similar although perhaps not identical in all forms of ANCA-associated vasculitis),[98,103] the disease of MPA in other organs is difficult to distinguish from that of other

forms of small-vessel vasculitis by light microscopy. The ANCA-associated vasculitides are more likely to involve small arteries and arterioles than are vasculitides associated with immune complexes, but involvement of capillaries and venules is the most common site in all forms of small-vessel vasculitis.[103] The absence or paucity of immune complex deposition by immunofluorescence is helpful but not definitive, because immune deposits may have been consumed by phagocytes in lesions more than 48 hours old. A biopsy definitive for GPA should include necrotizing extravascular granuloma in addition to small-vessel vasculitis, but this combination of features is seen in a minority of biopsy specimens. Similarly, the combination of small-vessel vasculitis and eosinophil-rich necrotizing granuloma is seen in a minority of biopsy specimens in EGPA. Nevertheless, it is often important simply to confirm, by biopsy, the presence of vasculitis somewhere in a patient in whom MPA, GPA, or EGPA is likely, but nonvasculitic conditions are also considerations.

The presence of vasculitis, either proven by biopsy or strongly implied by documented mononeuritis multiplex,[58,97] is often essential to distinguish EGPA from the HES because only 40% of patients with EGPA test positive for ANCA, usually anti-MPO.[58,95] In turn, a high circulating eosinophil count or eosinophilic infiltration on biopsy distinguishes EGPA from MPA, GPA, and other forms of vasculitis. A high circulating eosinophil count is also often the clue that a patient has EGPA or HES rather than merely asthma and nasal polyposis.

One setting in which biopsy proof of GPA is highly desirable is in the ANCA-negative patient. Only 60% to 70% of patients with disease limited to the upper airway test positive for antibodies to PR3 or MPO, in contrast to 90% or more with systemic vasculitis.[48,49,67,68] Unfortunately, only approximately 20% of nasal biopsies will show the triad of granulomatous inflammation, necrosis, and vasculitis. Malignancies, nasal cocaine use, other chronic trauma, and a range of infections can also cause chronic inflammation, necrosis, and destruction of soft tissue and bone in the upper airway.[69,70] In the lung, GPA is one of many conditions that can cause nodules as a result of granulomatous inflammation[104]; it is presumed that the key feature of vasculitis is much more likely to be seen in an excisional biopsy than in a transbronchial or transthoracic needle biopsy.

Determination of disease activity in a patient with known AAV is challenging. Patients are susceptible to both systemic and localized infection as a result of the use of immune-suppressive drugs and to poor drainage of secretions resulting from damage to the airway, and symptoms of these infections are similar to symptoms of AAV. Fluctuation in symptoms when patients have had significant organ damage—such as the airway in GPA, congestive heart failure, particularly in EGPA, or peripheral neuropathy in all forms of AAV—may occur with or without active disease. Musculoskeletal and constitutional symptoms can occur in a wide range of acute and chronic conditions, and most patients with AAV report some degree of chronic fatigue regardless of their apparent disease status. Perhaps the greatest challenge is excluding active renal inflammation in a patient with prior kidney damage because proteinuria and hematuria can persist without evidence of additional renal damage over long periods,[105] and gradual loss of remaining kidney function may be attributable to "grumbling" disease but also may occur without any evidence of active inflammation.[53]



## TREATMENT

A retrospective study by Walton[106] published in 1958 showed that, without treatment, the median survival of patients with GPA was approximately 5 months, and that 81% of patients died within 1 year of diagnosis. Death was primarily due to progressive failure of multiple organ systems. The use of corticosteroids for treatment extended the median survival time to approximately 12.5 months.[107] The dismal prognosis for these diseases was not reversed until alkylating agents were used beginning in the 1960s.[107] Current treatment regimens aim to induce remission and then maintain remission using less toxic agents. Treatment is tailored to disease severity, with organ- and life-threatening manifestations warranting the most aggressive therapy (summarized in Figure 89-8). EULAR has presented guidelines for the management of primary small- and medium-vessel vasculitis.[108]

### Induction of Remission for Granulomatosis with Polyangiitis and Microscopic Polyangiitis

Since the 1960s, oral cyclophosphamide, an alkylating agent derived from nitrogen mustard, has been used at a dose of 2 mg/kg/day, along with corticosteroids, to induce remission for GPA and MPA. When oral cyclophosphamide is used, remission rates for ANCA-associated vasculitis range from 75% to 93%[48,109]—a stark contrast to the dismal median survival time prior to the use of this medication. In initial treatment regimens, cyclophosphamide was used continuously for at least 1 year. However, this prolonged use was associated with significant adverse effects. In a study of 158 patients with ANCA-associated vasculitis who were treated with cyclophosphamide for least 6 months, 46% experienced a serious infection (including pneumonias, skin infections, and bacterial and fungal sepsis), 43% experienced cyclophosphamide-induced cystitis, 2.8% experienced bladder cancer (a 33-fold increase), and 1.3% experienced lymphoma (an 11-fold increase). The risk of malignancy after cyclophosphamide use has been shown to be dose dependent. Among women between 18 and 35 years of age, 57% had cessation of menses for at least 1 year, were unable to become pregnant, or had laboratory evidence of ovarian failure.[48] In part to minimize toxicity, some studies have adjusted cyclophosphamide dosing based on renal dysfunction or advanced age. However, these adjustments have not been consistent across clinical trials. Given the toxicities observed with prolonged cyclophosphamide use, alternative cyclophosphamide regimens to minimize toxicities have been sought.

One alternative to daily oral cyclophosphamide for remission induction is to use intravenous (IV) pulse cyclophosphamide. In the CYCLOPS trial, 149 patients with either GPA or MPA received prednisolone and were randomized to receive pulse cyclophosphamide (15 mg/kg IV every 2 weeks × 3 doses, then 15 mg/kg IV every 3 weeks until remission, and then continued for 3 more months) or oral cyclophosphamide (2 mg/kg/day until remission, then

1.5 mg/kg/day × 3 more months). After receiving cyclophosphamide, all patients received azathioprine. In the pulse cyclophosphamide arm, the mean cumulative dose was approximately half of the daily oral arm (8.2 g vs. 15.9 g), and consequently, less leukopenia was observed in the pulse arm. The median time to remission was approximately 3 months for both groups, and there was no difference in improvement in renal function between both groups.[62] Long-term follow-up (median duration 4.3 years) showed no difference in survival or renal function but a higher rate of relapse in the pulse arm compared with the daily oral arm (39.5% vs. 20.8%; HR for relapse in the daily oral arm, 0.50; 95% CI, 0.26 to 0.93; $P = 0.029$).[110]

Another alternative to daily oral cyclophosphamide for remission induction is the use of rituximab, a monoclonal antibody directed CD20, which is expressed on developing B cells from the immature B cell to the blast B cell stages. The mechanism of action for this antibody is not clearly known, but it can induce apoptosis of these developing B cells after binding and induce B cell depletion. Of note, B cell stem cells and plasma cells do not express CD20 and thus are not affected by rituximab. In the Rituximab in ANCA-Associated Vasculitis (RAVE) trial, which was double-blinded and designed to test for noninferiority, 197 patients with GPA or MPA received corticosteroid therapy and were randomized to receive either oral cyclophosphamide (2 mg/kg/day) or IV rituximab (375 mg/m$^2$ weekly × 4 doses). Patients in the oral cyclophosphamide arm were switched to azathioprine (2 mg/kg/day) after achieving remission with 3 to 6 months of cyclophosphamide therapy; patients in the rituximab arm were switched to oral placebo after the completion of four infusions. At the 6-month primary endpoint, rituximab was not inferior to cyclophosphamide at inducing remission and was potentially superior to cyclophosphamide for patients with relapsing disease. No difference was found in remission rates based on type of renal involvement, presence of alveolar hemorrhage, ANCA specificity or disease type, or whether patients became ANCA negative during the course of treatment.[65] In the 18-month follow-up study, a single course of rituximab continued to be noninferior to oral cyclophosphamide followed by azathioprine for remission maintenance. No significant difference was found between duration of complete remission, severity of relapses, or rate of adverse

events.[111] In the Rituximab versus Cyclophosphamide in ANCA-associated Vasculitis (RITUXVAS) trial, 44 patients newly diagnosed with ANCA-associated vasculitis were randomized (3 : 1) to receive rituximab along with only two infusions of cyclophosphamide versus IV cyclophosphamide for 3 to 6 months, followed by azathioprine. Rates of sustained remission and median increase in glomerular filtration rates at 12 months were similar in both groups. Rates of severe adverse events and death were also similar.[112] Both of these studies indicate that rituximab is comparable in efficacy to cyclophosphamide for remission induction.

Methotrexate has also been studied in comparison with oral cyclophosphamide for induction of remission of early systemic or localized disease. In the Nonrenal Wegener's Granulomatosis Treated Alternatively with Methotrexate (NORAM) trial, 100 patients with a new diagnosis of either MPA or GPA and without organ- or life-threatening manifestations such as severe hemoptysis, rapidly progressive neuropathy, or significant renal involvement (i.e., serum creatinine >1.7 mg/dL or 150 μmol/L, urinary red blood cell casts, or proteinuria >1 g/day) were randomized to receive either oral methotrexate up to 25 mg/week or cyclophosphamide, 2 mg/kg/day. Both treatment groups received maintenance therapy for 10 months, and then therapy was tapered and discontinued by month 12. At 6 months, the remission rate was similar in both groups (89.8% in the methotrexate arm and 93.8% in the cyclophosphamide arm, $P = 0.041$). In the methotrexate arm, remission was delayed for patients with more extensive disease or pulmonary involvement, and the relapse rate was higher at 18 months (69.5% in the methotrexate arm vs. 46.5% in the cyclophosphamide arm). Thus, although methotrexate was able to induce remission in patients without organ or life-threatening involvement, it was less effective than cyclophosphamide. Given the high relapse rate observed for both the methotrexate and cyclophosphamide treatment arms, therapy for these diseases should be continued beyond 12 months.[113]

More recently, abatacept has been studied as a remission induction agent for nonsevere, relapsing GPA. The addition of this agent to prednisone and remission maintenance therapy (e.g., methotrexate, azathioprine, or mycophenolate mofetil) was associated with disease remission and reduction in glucocorticoid doses.[114] The efficacy of this agent is being investigated in a larger trial (ClinicalTrials.gov identifier: NCT02108860).

Mycophenolate mofetil has been studied as a remission induction alternative to cyclophosphamide. In the Mycophenolate Mofetil versus Cyclophosphamide for Remission Induction of ANCA-associated Vasculitis (MYCYC) trial, 140 patients were randomized to receive either mycophenolate mofetil (2000 to 3000 mg/day) versus IV pulse cyclophosphamide. Initial results suggest that the primary remission endpoint (absence of disease activity ≥4 weeks while adherent to the glucocorticoid regimen) was reached by a similar proportion in each treatment arm (66% in the mycophenolate mofetil arm vs. 69% in the cyclophosphamide arm). However, the rate of relapse was substantially higher in the mycophenolate mofetil arm. Full publication of these results is needed to determine efficacy of mycophenolate mofetil for remission induction in the ANCA-associated vasculitides.[115,116]

## Maintenance of Remission for Granulomatosis with Polyangiitis and Microscopic Polyangiitis

Given the toxicities associated with prolonged cyclophosphamide use, a common strategy is to "induce" remission using more toxic therapies such as cyclophosphamide and then "maintain" remission using a less toxic therapy, thus decreasing overall toxicity due to cyclophosphamide. Medications studied as remission maintenance agents include azathioprine, methotrexate, mycophenolate mofetil, leflunomide, trimethoprim/sulfamethoxazole, etanercept, and rituximab.

Azathioprine was first demonstrated to be an effective remission maintenance agent in the Randomized Trial of Maintenance Therapy for Vasculitis Associated with Antineutrophil Cytoplasmic Autoantibodies (CYCAZAREM) trial, which treated 155 patients newly diagnosed with GPA or MPA with oral cyclophosphamide for at least 3 months and then randomized patients to continue cyclophosphamide or switch to azathioprine (2 mg/kg/day). The rate of relapse was similar in both groups (15.5% in the azathioprine arm vs. 13.7 in the cyclophosphamide arm, $P = 0.65$), as was the rate of adverse events. This study was the first to indicate that the duration of cyclophosphamide therapy could be reduced without significant adverse effects.[63]

Methotrexate was shown to be equally efficacious for remission maintenance when compared with azathioprine. In this study, 129 patients with GPA or MPA who achieved remission with cyclophosphamide therapy were randomized to receive either azathioprine (2 mg/kg/day) or methotrexate (up to 25 mg/week) for 12 months. The two medications were shown to have similar rates of remission maintenance, as well as adverse events, at 28 months of follow-up. Of note, 73% of patients relapsed after discontinuing the study medication at 12 months.[64] Long-term follow-up of the patients in this trial (median duration 11.8 years) showed no difference in overall 10-year survival rate, adverse event, or relapses. Anti-PR3 positivity was significantly prognostic of long-term relapses.[117]

Mycophenolate mofetil has also been investigated as an alternative remission agent in the International Mycophenolate Mofetil Protocol to Reduce Outbreaks of Vasculitides (IMPROVE) trial. After remission induction with cyclophosphamide, 156 patients were randomized to receive either azathioprine (2 mg/kg/day) or mycophenolate mofetil (2000 mg/day) and were followed up for a median of 39 months. Relapses were more common in the mycophenolate arm (HR for relapse in the mycophenolate arm, 1.65; 95% CI, 1.06 to 2.70; $P = 0.03$). Secondary outcome measures such as renal function and proteinuria and severe adverse event rates did not differ between groups.[118] Thus mycophenolate mofetil is believed to be less effective than azathioprine in maintaining remission in ANCA-associated vasculitides.

In a trial of 54 patients randomized to receive either leflunomide (30 mg/day) or methotrexate (starting at 7.5 mg/week and reaching 20 mg/week after 8 weeks), patients in the leflunomide arm had a decreased rate of relapse at 6 months (6/26 in the leflunomide vs. 13/28 in the methotrexate arm). A higher rate of major relapses in the methotrexate arm led to an early termination of the study. However, adverse event rates were higher in the

leflunomide arm.[119] Thus additional studies are needed to determine the role of leflunomide for remission maintenance therapy.

After reports of a beneficial effect of trimethoprim/sulfamethoxazole for the treatment of GPA, a double-blinded clinical trial randomized 81 patients with GPA who were in remission to receive either co-trimoxazole (800 mg of sulfamethoxazole and 160 mg of trimethoprim) or placebo for 24 months. A higher proportion of patients in the co-trimoxazole arm remained in remission compared with the placebo arm (82% vs. 60%). A subgroup analysis showed that patients with nasal or upper airway lesions benefited the most from co-trimoxazole use.[120] Thus, although co-trimoxazole is not commonly used for remission maintenance in persons with ANCA-associated vasculitis, it may be beneficial for patients with nasal or upper airway manifestations.

TNF inhibitors have had significant success as disease-modifying therapy for other autoimmune illnesses such as rheumatoid arthritis and inflammatory bowel disease. Past case series have suggested that agents such infliximab may be efficacious in controlling disease activity in GPA and MPA.[121] The most rigorously studied TNF inhibitor in GPA and MPA is etanercept for the maintenance of remission. In the Wegener's Granulomatosis Etanercept Trial (WGET), 174 patients received standard remission induction therapy (cyclophosphamide or methotrexate) and were randomized to receive concomitant etanercept or placebo, which was continued during the remission maintenance phase. There was no statistical difference in the rate of sustained remission between the etanercept and placebo arms (69.7% vs. 75.3%, $P = 0.39$) or in the time to remission. However, the incidence of solid cancers was significantly higher in the etanercept arm (six cancers vs. none, $P = 0.01$), suggesting that combining cyclophosphamide therapy with TNF therapy can substantially increase one's risk of cancer.[122] Based on these results, TNF inhibitors are generally not used for remission maintenance for ANCA-associated vasculitis.

Given the success of rituximab as a remission induction agent, it was also investigated as a remission maintenance agent. Previously published case series showed prolonged B cell depletion with rituximab to be effective in maintaining remission.[123-125] The use of rituximab as a remission maintenance agent has been more formally studied in the Maintenance of Remission using Rituximab in Systemic ANCA-associated Vasculitis (MAINRITSAN) trial. In this study, 115 patients with either GPA, MPA, or renal limited vasculitis were randomized to receive either azathioprine (2 mg/kg/day × 12 months, followed by 1.5 mg/kg/day × 6 months, then 1 mg/kg/day × 4 months) or rituximab (500 mg IV × 2 doses at study entry and then every 6 months × 18 months), after having remission induced with cyclophosphamide. At 28 months (the primary endpoint), the major relapse rate was significantly lower in the rituximab arm (5% in the rituximab arm vs. 29% in the azathioprine arm).[126] The frequency of severe adverse events, including severe infections and malignancy, were similar in both arms. This difference in relapse rate has persisted at 39 months of follow-up (12.7% in the rituximab arm and 48.1% in the azathioprine arm; HR for relapse in the rituximab arm, 0.20; 95% CI, 0.11 to 0.45; $P < 0.0001$).[127] The international, open label, randomized controlled trial comparing rituximab with azathioprine as maintenance therapy in relapsing ANCA-associated vasculitis (RITAZAREM) trial is currently under way to further investigate the efficacy of rituximab (1000 mg IV every 4 months × 5 doses) as a remission maintenance agent.[128]

The use of low-dose glucocorticoids (prednisone or prednisolone, 5 to 10 mg/day) as a standard component of maintenance therapy is a source of considerable controversy and varying practice among experts worldwide. Unfortunately, no randomized trial investigating this question has been performed. Comparing relapse rates between trials is problematic because of different treatment regimens, different percentages of anti–MPO-positive patients or newly diagnosed patients, and different definitions of remission and relapse. With these caveats, a recent meta-analysis showed that trials that routinely continued glucocorticoids for 12 to 18 months reported markedly lower relapse rates than those in which they were discontinued earlier, usually by month 6.[129]

## Adjunctive and Alternative Agents

The role of plasma exchange in the treatment of ANCA-associated vasculitis was investigated in the Methylprednisolone or Plasma Exchange for Severe Renal Vasculitis (MEPEX) trial. In this trial, 137 patients with newly diagnosed GPA or MPA who had renal involvement confirmed by biopsy and serum creatinine greater than 5.8 mg/dL (500 μmol/L) were randomized to receive either seven plasma exchanges or 3000 mg of IV methylprednisolone, in addition to cyclophosphamide and prednisone. When compared with IV methylprednisone, plasma exchange was associated with a 24% decrease in risk to progression to end-stage renal disease at 12 months. No difference in survival was observed.[130] This therapy is being investigated further in a large ($n > 500$), multicenter, international trial (PEXIVAS[131]).

Intravenous immunoglobulin (IVIG) has been considered for patients who are unable to receive conventional immunosuppressive therapy. Case series using IVIG for remission induction have had conflicting results. In a randomized, placebo-controlled trial of 17 patients who received a single dose of IVIG (2000 mg/kg), 14 patients had significantly reduced disease activity, but this effect did not persist beyond 3 months.[132] Larger controlled clinical trials are needed to fully understand the efficacy of this agent for the treatment of ANCA-associated vasculitides.

Other alternative therapies for AAV investigated in smaller studies include anti-thymocyte globulin, which causes T cell depletion,[133] deoxyspergualin, which inhibits T cell maturation,[134] and alemtuzumab (Campath, anti-CD52), which depletes both T cells and B cells.[135]

## Treatment of EGPA

The optimal treatment of EGPA is less clearly defined when compared with GPA and MPA. In part because of the differences in clinical manifestations, patients with EGPA are frequently excluded from the randomized clinical treatment trials of GPA and MPA. Even so, the treatments found to be efficacious for GPA and MPA are used to treat EGPA,

and the same general therapeutic strategy of inducing remission with a more toxic medication and maintaining remission with a less toxic medication is also applied.

The vasculitis and asthma manifestations of EGPA are usually managed separately. Asthma treatment generally follows recommended asthma treatment guidelines for patients without EGPA. However, many patients' asthma symptoms are corticosteroid dependent, and thus additional immunosuppression can be used for steroid-sparing effects. Initial management of systemic or vasculitic manifestations of EGPA relies on corticosteroids. Patients with EGPA who do not have poor prognostic factors as defined by the original Five Factor Score (serum creatinine >1.58 mg/dL, proteinuria >1 g/day, severe GI involvement, cardiomyopathy, or CNS involvement) can be treated with corticosteroids alone, but 35% of patients relapse when corticosteroids are tapered.[136] Other immunosuppressive agents are needed in addition to corticosteroids for patients with more severe disease. As with GPA and MPA, cyclophosphamide is generally used to treat organ- or life-threatening manifestations.[137] The remission maintenance agents discussed in the previous section have not been well studied in EGPA. One randomized, open-label study showed that azathioprine was efficacious for remission maintenance when compared with cyclophosphamide,[136] but whether the efficacy of one agent such as azathioprine is equivalent or superior to the other remission-maintenance agents is unknown. For patients with and without poor prognostic factors, approximately 80% of patients require long-term use of corticosteroids to manage manifestations such as asthma.[136,137]

Current understanding of the efficacy of rituximab in EGPA is derived from case reports and case series. Most patients with EGPA in the reports were treated with rituximab because of disease refractory to usual treatments (e.g., cyclophosphamide) or medication intolerance. In one of the largest case series to date, nine patients with EGPA refractory to conventional therapy were treated with rituximab at a single center. All nine patients were either in complete or partial remission within 3 months after treatment. No flares were observed for three patients who were preemptively treated with rituximab (median follow-up for 3 years).[138] Larger studies and more experience are needed to fully determine the efficacy of rituximab in EGPA.

A promising therapy for EGPA is mepolizumab, a monoclonal antibody directed against IL-5, a cytokine critical for activation of eosinophils. Previous experience with mepolizumab in HES showed prompt normalization of peripheral eosinophil counts, as well as decreased glucocorticoid usage.[139] In two uncontrolled pilot studies of mepolizumab in EGPA, mepolizumab use led to decreased disease activity, normalization of eosinophil counts, and reduction of corticosteroid use. However, cessation of mepolizumab use was associated with disease flares.[140,141] A randomized, double-blinded, placebo-controlled trial using mepolizumab in EGPA is currently under way (ClinicalTrials.gov identifier: NCT02020889).

## OUTCOMES

Although the ANCA-associated vasculitides are still sometimes fatal (particularly as a result of alveolar hemorrhage) because of the severity of disease at onset or treatment resistance, most patients can be successfully treated, which has two important sequelae. First, the substantially increased risk of mortality in the first 6 months after diagnosis (approximately 10%) is mostly due to infection as a consequence of treatment, rather than vasculitis itself.[142] Second, the moderately increased risk of mortality long term is multifactorial, including infection, cardiovascular disease, and malignancy. The importance of permanent organ damage in increasing mortality is clear from the finding that the only factor other than advancing age that is strongly associated with long-term mortality in MPA and GPA is renal dysfunction.[142] Analogously, cardiomyopathy is by far the strongest risk factor for mortality in EGPA.[54]

Although mortality has been greatly reduced, morbidity remains high because of permanent damage (particularly renal insufficiency, sinonasal symptoms, hearing loss, neuropathy, and dyspnea) and consequences of treatment (diabetes, hypertension, osteoporosis, weakness, and certain malignancies).[92] It is also notable that patients report fatigue and reduced energy—symptoms that cannot be assessed objectively—as the most important negative consequences of having vasculitis.[143]

The incidence of cancer has been reported to be elevated in GPA. A recent study showed lower risks of bladder cancer, leukemia, and lymphoma than had been reported previously.[144,145] Because strikingly increased risk of all three of these cancers had been observed after long-term use of cyclophosphamide, it is likely that there is little increased risk with current approaches to treatment. There remains an increased risk of nonmelanoma skin cancer,[144,145] and it is difficult to assess relative risks of uncommon cancers in rare diseases.

Assuming the success of initial treatment, the different forms of AAV often relapse but often do not. Based on cohorts and follow-up of patients in clinical trials of patients with systemic vasculitis, the risk of relapse in GPA is about 60%,[48,49,111,146,147] and that of MPA is about 30%.[53,111,146-148] Whether this difference is due to the disease phenotype or ANCA specificity is uncertain.[111,146,147] Drawing a firm conclusion would require longitudinal follow-up of large numbers of MPO-positive patients with GPA separately among white and Asian cohorts, because that phenotype is more common among Asian patients.[56,90] Not surprisingly, having relapsed in the past also increases the risk of subsequent relapses.[111] Localized/limited GPA may have a higher rate of relapse than systemic/severe GPA,[67,68] and 30% to 55% of such patients may be ANCA-negative.[67,68]

Persistence of c-ANCA/PR3 and rising titers were associated with increased risk of flare in most but not all studies. The likelihood ratio is approximately 2, that is, below the level considered to be "diagnostic" for making treatment decisions with confidence.[149] Almost all studies on the value of following up on ANCA titers have focused on c-ANCA/PR3.

Relapse of vasculitis or parenchymal eosinophilic disease above and beyond sinonasal disease and asthma is about as common in EGPA as in MPA and is somewhat more common in ANCA-positive than in ANCA-negative patients.[54] Relapses of sinonasal disease and asthma are much more common (often chronic) and are the main reason that more than 80% of patients with EGPA need to

continue to take prednisone and often additional immunosuppressive drugs.[54]

The caveat to interpreting studies of relapse rates is that there may be selection bias: patients with more severe disease are more likely to enroll in clinical trials, and patients with relapsing disease are more likely to continue to be followed at referral centers. Thus the course of mild MPA (e.g., purpura, myalgia, and anti-MPO antibodies) is virtually unknown, and chronically localized/limited GPA has not been studied—in trials or outcome studies—as extensively as has systemic/severe disease.[67]

## PATHOGENESIS

MPA, GPA, and EGPA all feature leukocytoclastic vasculitis: fibrinoid necrosis of arterioles, capillaries, and venules by neutrophils, which infiltrate and die in the surrounding tissue and leave characteristic fragments of their nuclei visible under the microscope. Additional involvement of small arteries is sometimes seen, and involvement of small veins is rare.[103] Although some deposition of immunoglobulins and complement can be seen (these diseases are "pauci-immune" rather than nonimmune),[103,150] immune complex deposition is thought to play little if any role in pathogenesis. Because ANCA are highly associated with pauci-immune necrotizing vasculitis, much of the study of pathogenesis has focused on the generation and mode of action of ANCA.

Although the bulk of MPO and PR3 is intra-cellular in neutrophil granules, these proteins may be translocated to the cell surface either constitutively or by inflammatory stimuli[151] and serve as targets for ANCA to activate neutrophils.[152,153] In addition, MPO and PR3 may serve as targets extra-cellularly after degranulation, or particularly after release associated with neutrophil extra-cellular traps.[153]

The best evidence that ANCA are directly pathogenic comes from a mouse model in which anti-MPO antibodies (produced by immunizing *Mpo*–/– mice with mouse MPO) produce pauci-immune GN when transferred into normal mice.[154] Neutrophils and activation of the C5 component of complement are required to produce GN.[155-157] However, other features than GN are not seen, and GN itself is relatively mild.[154,158] More severe GN and additional features of systemic vasculitis are produced by transferring spleen cells into SCID mice,[154] but whether all of this disease is attributable to anti-MPO antibodies or even to MPO-specific T cell immunity is unclear.

Efforts to produce an analogous model using PR3 have not been successful, and other efforts to demonstrate pathogenicity of anti-PR3 autoimmunity require considerable experimental manipulation and produce limited disease. Whether this difficulty is due to the different structure and biology of PR3 in humans and rodents—or is evidence that anti-PR3 antibodies have limited pathogenicity in isolation—is not clear. Production of vasculitis using human anti-PR3 antibodies and mice with "humanized" immune systems supports the human-versus-mouse explanation and may provide the best evidence in favor of anti-PR3 antibodies causing vasculitis,[159] but as with all other rodent models of ANCA-associated vasculitis, this one has pros and cons for inferring the pathophysiology of human disease.[158] Mouse models of HES have been developed,[160] but not the combination of eosinophilic and necrotizing vasculitis that would be a more specific model for EGPA.

T cell immunity is implicated in any process that results in high-affinity antibodies, but in addition, $CD4^+$ T cells are found in the necrotizing granulomatous lesions in GPA and are likely involved in macrophage activation and neutrophil recruitment locally.[161] The target antigen(s) is/are unclear, particularly because a large percentage of patients lacking evidence for systemic vasculitis test negative for circulating ANCA. Multiple changes in the percentages of T cell subsets—Th1, Th2, Th17, and regulatory T cells—have been described in patients with different forms of AAV, in different tissue sites, and in different stages of disease activity.[161]

The number of circulating proteins related to immunity, inflammation, vascular injury, and tissue repair is so large in highly active GPA and MPA that it is difficult to obtain insight into pathophysiology from biomarker studies.[162,163] In EGPA, circulating products of eosinophils are elevated in untreated disease.[164] As expected, markers of Th2 responses are elevated,[165-167] but Th17 cells have recently been implicated as well.[166-168]

As noted in the Epidemiology and Genetics sections, known genetic risk factors and environmental exposures explain only a small portion of the risk for GPA, MPA, or EGPA. Although it is possible that rare or unique (including somatic) genetic mutations or rare environmental exposures may contribute further to risk, it is also worth emphasizing that in many autoimmune diseases, random chance is likely to play an important role in determining whether tolerance to a particular autoantigen is broken.

## CONCLUSION

In the past 30 years, significant progress has been made in diagnosing and treating ANCA-associated vasculitis. Although this progress has dramatically reduced the mortality of the AAV, patients continue to accumulate organ damage because of the chronic relapsing nature of these diseases. Thus many challenges remain. Clinicians and investigators alike would benefit from an improved understanding of the role of ANCA in disease pathogenesis, identification of clinically actionable biomarkers of disease activity, and the development of more targeted therapies to reduce treatment toxicity. With this additional knowledge, the prognosis for patients AAV may continue to improve.

CHAPTER 90

# Polyarteritis Nodosa and Related Disorders

Raashid Luqmani

**KEY POINTS**

- Polyarteritis nodosa (PAN), which is characterized by vasculitis of medium-sized arteries with few or no immune deposits, is relatively rare, especially in comparison with anti-neutrophil cytoplasmic antibody (ANCA)–associated small-vessel vasculitis.
- One form of PAN that is now uncommon is caused by hepatitis B virus and usually responds well to anti-viral therapy, plasma exchange, and/or glucocorticoids. Non–hepatitis B–associated PAN should be treated aggressively with cyclophosphamide and glucocorticoids, using the same approach as that used for systemic ANCA-associated vasculitis.
- The incidence and prevalence of non-hepatitis PAN is around 1 per million per annum. A significant reduction in the incidence of PAN has occurred because of a decreasing incidence of hepatitis B infection, as well as reclassification of patients (i.e., better case recognition of ANCA-associated vasculitis).
- Presenting features of PAN include an insidious onset of weight loss, purpuric skin lesions together with mononeuritis multiplex, and symptoms of mesenteric ischemia.
- Glomerular renal disease is absent in people with PAN and should prompt consideration of other diagnoses, especially ANCA-associated small-vessel vasculitis.
- Hematuria with renal impairment is rare in people with PAN but can occur as a result of renal infarction.
- "Cutaneous PAN" is a limited form of vasculitis that is unrelated to systemic PAN.
- Buerger's disease (thromboangiitis obliterans) affects both sexes and involves the upper and lower extremities; the role of tobacco use in Buerger's disease is established but not understood.
- The evidence base for treatment of other rare forms of vasculitis is limited.

## POLYARTERITIS NODOSA

### Definition and Classification

The term *periarteritis nodosa* was originally introduced in 1866 and was subsequently used to describe any form of systemic vasculitis.[1] The term has been modified to polyarteritis nodosa (PAN), and the definition has been revised to consist of "necrotizing inflammation of medium-sized or small arteries without glomerulonephritis or vasculitis in arterioles, capillaries, or venules."[2]

The American College of Rheumatology (ACR) criteria, which were designed to classify patients as having PAN to distinguish them from patients with other forms of primary systemic vasculitis, are of limited use because they do not differentiate between PAN and microscopic polyangiitis (MPA); both conditions are included under the umbrella of PAN. Three of 10 ACR criteria (listed in Table 90-1) are required to make a diagnosis.[3]

The sensitivity of the ACR criteria for PAN (or MPA) is 82.2%, with a specificity of 86.6% when used to classify the disease.[3] Definitions of vasculitis (including PAN) were published in 1994 by the Chapel Hill Consensus Conference (CHCC)[2] and updated in 2013.[4] MPA, granulomatosis with polyangiitis (GPA), and eosinophilic granulomatosis with polyangiitis (EGPA; formerly Churg-Strauss syndrome) were distinguished from PAN on the basis of the pathologic findings of small-vessel involvement in the former three diseases; by contrast, small-vessel involvement is absent in PAN.

Much confusion continues to exist regarding the terms used to describe patients with different forms of vasculitis. It is worth considering this issue for a moment because, upon reviewing the cases of patients whose disease has previously been given the label of "PAN," the clinical features at presentation very often indicate another form of vasculitis, typically MPA or GPA. In an attempt to rationalize the naming of different forms of vasculitis, the European Medicines Agency (EMA) produced an algorithm to assist in the classification of patients with systemic small- and medium-vessel primary systemic vasculiti.[5] A decision tree approach was used, effectively putting PAN at the bottom of the tree.[5] In other words, patients were assigned to any other form of vasculitis when possible, and the term *PAN* was applied only as a last resort when no other diagnosis was made. This might seem like a rather negative view of the condition, but after accounting for the overuse of the term PAN in preference to other terms in the past, the true incidence and prevalence of PAN are actually low.

The EMA algorithm is particularly useful because MPA is a more common condition than PAN but is not included in the ACR classification criteria (it is considered part of PAN), whereas in the CHCC definition, PAN and MPA are treated as separate entities. Important differences exist between PAN and MPA in terms of pathogenesis, organ involvement, tendency to relapse, and prognosis.[6] In the CHCC definition, PAN is a medium-vessel disease; by comparison, MPA is predominantly a small-vessel disease that includes glomerulonephritis and pulmonary capillaritis.[2]

**TABLE 90-1** American College of Rheumatology Criteria for Classification of Polyarteritis Nodosa

| |
|---|
| Weight loss ≥4 kg |
| Livedo reticularis |
| Testicular pain or tenderness |

PAN, Polyarteritis nodosa.

Modified from Henegar C, Pagnoux C, Puéchal X, et al: A paradigm of diagnostic criteria for polyarteritis nodosa: analysis of a series of 949 patients with vasculitides. *Arthritis Rheum* 58:1528–1538, 2008.

Patients are assessed using the EMA algorithm if they have a clinical diagnosis of an anti-neutrophil cytoplasmic antibody (ANCA)–associated vasculitis or PAN. In the algorithm, PAN is regarded as a diagnosis of exclusion. The first part of the algorithm is to determine if the patient's disease fulfills the Lanham[7] or ACR criteria[8] for EGPA. If it does fulfill the criteria, the patient's disease is classified as EGPA. If not, the next step is to determine if the patient's disease fulfills the ACR criteria or CHCC definition for GPA,[2,9] either through histologic evidence or with appropriate surrogate markers and a positive ANCA test. If not, one proceeds down the algorithm to see if the patient's disease fulfills the definition of MPA,[2] with histology showing small-vessel vasculitis or glomerulonephritis and no surrogate markers for GPA, or surrogate markers of glomerulonephritis and a positive ANCA test. Only when EGPA, GPA, and MPA are excluded is a diagnosis of PAN possible in this schema. To fulfill the definition of PAN in this algorithm, histologic or angiographic features must be present that are consistent with the diagnosis. The disease of any remaining patients is determined to be unclassifiable. The initial validation of the algorithm made use of paper cases that were assessed by a number of experts in vasculitis. In fact, every case was assigned to one of the conditions, without the need to describe any case as unclassifiable. This outcome may not reflect clinical practice, in which some patients appear to have an overlap between different forms of vasculitis or incomplete forms of a particular vasculitis. This important issue has begun to be addressed by a task force on classification and diagnostic criteria in vasculitis.[10,11]

The French Vasculitis Study Group proposed a set of predictive items (Table 90-2) to be used as diagnostic criteria.[12] The items were derived from 949 patients with known vasculitis (including 262 patients described as having PAN) and not from undifferentiated patients, and therefore they are actually another form of classification criteria.

The combination of nonspecific constitutional symptoms and ischemic symptoms in one or more organ systems should alert the physician to the possibility of a systemic vasculitis. PAN typically presents with nonspecific symptoms, such as fever, weight loss, and myalgia, in combination with single or multiorgan manifestations resulting from ischemia or infarction. The most common organ manifestation is neurologic with mononeuritis multiplex, followed by skin lesions, abdominal pain from mesenteric ischemia, and renal infarction. Testicular pain due to ischemic orchitis is a classic feature of PAN but is rare at presentation. Some patients may present with acute abdomenal symptoms requiring surgery as a result of bowel, liver, spleen, or pancreatic infarction. Myocardial infarction, ischemic cardiomyopathy, optic ischemia, and ischemic complications of the female genital tract are possible but unusual.

## Epidemiology

The epidemiology of PAN has changed over time. Effective hepatitis B virus (HBV) immunization programs, improved blood screening for HBV, and major changes in the definition and classification of vasculitis have resulted in a substantial reduction in the true incidence of what we call PAN. Before the CHCC definition in 1994, MPA was included in the incidence and prevalence estimates of PAN, the impact of which is highlighted in a study comparing the incidence of PAN in three European regions: 4.4 to 9.7 per million by the ACR criteria versus 0 to 0.9 per million with the CHCC definition.[13]

According to ACR criteria, the incidence of PAN is 2 to 9 per million in Europe and the United States.[14] A higher incidence of 16 per million (by CHCC definition) is reported in Kuwait,[15] and 77 per million is described in an Alaskan population endemic for HBV, although it was based on only 13 actual cases of HBV PAN (in a study performed before ACR criteria or CHCC definitions were available).[16] The prevalence of PAN by ACR criteria is 31 to 33 per million in Western Europe[17-19]; it is 2 to 9 per million in Germany by CHCC definition.[20] A small study from Australia assessed the incidence and prevalence of different

forms of vasculitis between 1995 and 2005 in one area, suggesting a decrease in the incidence of PAN from 2.3 per million per annum to 1.1 per million per annum.[21]

A study from 2009 assessed the incidence and survival of patients with different forms of vasculitis and estimated the incidence of PAN to be 0.9 (between 0 and 1.7) per million per annum. This estimate compares with an almost 10-fold difference in the incidence of GPA and MPA (between 9.8 and 10.1 per million per annum).[22]

PAN can occur at any age, but the most common age range at diagnosis is 40 to 60 years. No clear gender difference exists.[19] In a multiethnic population from France, patients with European ancestry had a higher prevalence of PAN compared with patients without European ancestry.[18] Childhood-onset PAN is less common than adult-onset PAN, with a low risk of death (3.8% in a series of 52 children followed up for more than 6 years) but a significant risk of serious complications, including hypertension and cranial nerve palsy, which themselves predict worse outcome in terms of morbidity.[23]

## Etiology and Pathogenesis

PAN is often related to infection with hepatitis B.[24] The incidence of HBV-related PAN follows HBV infection rates, previously accounting for 7% to 38.5% of patients diagnosed with PAN.[18,25] The prevalence of HBV-related PAN has reduced in recent years as a result of vaccination for HBV and improved screening of blood products.[18,26] PAN develops in 1% to 5% of patients with HBV infection,[16] which confers an approximately 1000-fold increase in risk compared with the background population.[14] By contrast, in Alaska, an area endemic for HBV, a substantial increased annual incidence of HBV PAN is found (77 per million), primarily as a result of vertical transmission.[16] Documented exposure to HBV occurs from blood products, intravenous drug use, and sexual contact. Screening of blood products for HBV and mass vaccination against the virus has successfully reduced the incidence of HBV PAN, as shown in French patients, with the proportion of cases of PAN due to HBV falling from 38.5% in the 1970s to 17.4% by the period 1997-2002.[27]

In HBV-related PAN, the postulated mechanism of vasculitis includes direct vessel injury by replicating virus or deposition of immune complexes. Deposition of immune complexes leads to activation of the complement cascade, resulting in an inflammatory response and subsequent endothelial damage. The vasculitis typically occurs within the first few months after HBV infection and may be the first presenting feature of this infection. Evidence for the pathogenic nature of HBV and immune complexes is supported by the effectiveness of a treatment strategy to eradicate HBV with anti-viral therapy and removal of immune complexes by plasmapheresis without the need for long-term immunosuppression.[27,28]

Saadoun and colleagues[29] described 31 patients who had hepatitis C virus (HCV)–associated vasculitis, which they classified as PAN according to ACR criteria and CHCC definitions. This cohort, representing approximately one-fifth of their patients with HCV vasculitis, had more frequent fevers, weight loss, severe hypertension, gastrointestinal tract involvement, severe acute sensory-motor multifocal mononeuropathy, kidney and liver microaneurysms, and increased C-reactive protein compared with other patients with HCV vasculitis. In contrast, their response to therapy was more successful.

In the remainder of patients with PAN, the cause of the disease is unknown. Genetic, infectious, and environmental agents are thought to be important, but no conclusive evidence exists.[13]

A recent study of exome sequencing of six families in which multiple family members were affected has shown a link to a recessive loss of function mutation of adenosine deaminase 2.[30]

The response of idiopathic PAN to immunosuppressive therapy suggests an immunologic mechanism. In idiopathic PAN, the role of immune complexes is unclear. There is evidence of endothelial dysfunction, an increase in inflammatory cytokines, and an increase in expression of adhesion molecules. The inflammatory lesions have a propensity to occur at the sites of bifurcation in vessels, where turbulent flow is most likely. After the inciting event, focal and segmental necrotizing inflammation of medium- and small-sized arteries is present, which leads to intimal proliferation with subsequent thrombosis, resulting in ischemia or infarction of the organ or tissue supplied by these arteries.

Some case reports describe the development of PAN in patients with pre-existing hairy cell leukemia.[31,32] Most patients in these cases had undergone a splenectomy before the development of PAN. Potential mechanisms for the association between hairy cell leukemia and PAN include cross-reactivity of antibodies between tumor cells and the endothelium, direct damage of the endothelium by tumor cells, and local production of pro-inflammatory cytokines, triggering vessel wall damage.[32]

## Pathologic Features

Because of the protean manifestations of the disease, it might be appropriate to obtain biopsy specimens from several different sites when considering the diagnosis in any individual patient. Sampling should be directed by the pattern of clinical involvement suggested by the history or physical examination. Muscle, peripheral nerves, kidney, testis, and rectum, when involved, provide the best yield. However, skin involvement and positive results of a skin biopsy do not always indicate evidence of systemic involvement[33-35] (see section on cutaneous PAN).

A biopsy of a medium-sized artery will show "focal and segmental" transmural necrotizing inflammation[34,35] (Figure 90-1). If any clinical or laboratory features indicate involvement of small vessels, further assessment should be undertaken, because these features suggest an alternative form of vasculitis such as MPA.[36]

Inflammatory change at the bifurcation of vessels is reported to be common. The coexistence of different stages of inflammation and scarring, as well as normal vessel wall, is typical in patients with PAN. Areas of acute inflammation will usually have a pleomorphic cellular infiltrate of lymphocytes, neutrophils, macrophages, and eosinophils. Aneurysms can occur at the site of active lesions, and this morphologic appearance is what led to the term "nodosa" (Figure 90-2). Proliferative scarring in other areas may lead to narrowing of vessels.[33-37]

**Figure 90-1** This celiac axis angiogram from a patient with polyarteritis nodosa demonstrates an irregular vascular pattern with small aneurysms in the hepatic vessels.

**Figure 90-2** Broken livedo in a patient with cutaneous polyarteritis nodosa. *(Courtesy Professor Sunderkoetter, Department of Dermatology, University Hospital of Muenster.)*

## Clinical Features

Although PAN can present at any age, it typically occurs in the age range of 40 to 60 years. No significant gender difference exists. The diagnosis can be difficult to make because individual features can occur in a variety of other diseases. Table 90-3 summarizes the clinical findings in PAN. The presence of nonspecific constitutional symptoms such as fever, weight loss, joint and muscle pains (found in 65% to 80% of cases of PAN), and ischemic symptoms in one or more organ system should raise the possibility of a systemic vasculitis.[19,37] Organ-specific manifestations may be present at the onset of disease, or more of a low-grade course may be present, resulting in the development of specific organ involvement months to years later. Involvement of organs may be in isolation or as multisystem disease.[38] In a Swedish series, the most common manifestations occurred at disease onset: nervous system (55%), skin (44%), abdominal (33%), and renal (11%).[19] A review of 348 patients diagnosed as having PAN since the 1960s[39] suggested that their mean age at diagnosis was 51 years and the most frequent symptoms were generalized features in more than 90% of cases, neurologic features in 79%, skin involvement in 50%, abdominal involvement in 36%, hypertension in 35%, renal artery microaneurysms in 66%, and histologically proven PAN in 70%. The subset of 123 patients with hepatitis B–associated PAN was more likely to experience peripheral neuropathy, abdominal pain, cardiomyopathy, orchitis, and hypertension compared with 225 non-HBV patients with PAN. The relapse rate was 22% over a follow-up of 6 years (28% for non–HBV-related PAN compared with 11% for HBV PAN). The mortality rate was 25% overall (20% for non-HBV PAN compared with 34% in HBV-related PAN). Five-year relapse-free survival was higher in patients with HBV-related PAN (67% compared with 59%). The conclusion was that non-HBV PAN in particular had a high mortality, especially involving elderly people and was worse in patients with skin manifestations.

## Clinical Assessment of Patients

In patients in whom vasculitis is suspected, a thorough history and physical examination is necessary to identify the potential organ systems involved. Use of the Birmingham Vasculitis Activity Score as a checklist of important features of the disease is recommended[40] to guide further targeted investigation and to be used subsequently in devising a management plan for treatment. Table 90-3 lists the typical features to be assessed in people suspected of having PAN. In up to 23% of cases, we should expect new disease manifestations to appear during follow-up,[41] emphasizing the need for regular review and evaluation in all patients.

## Laboratory Testing

No specific laboratory tests are available to diagnose PAN, but some tests may be useful to support the diagnosis, identify organs that may be affected, and rule out alternative diagnoses (Table 90-4).

## Radiology

The conventional fluoroscopic contrast angiogram traditionally has been the imaging modality of choice (Figure 90-1), but increasingly, it is being replaced by less invasive, safer techniques, such as computed tomography (CT) angiography or magnetic resonance (MR) angiography. The classic findings are multiple small aneurysms, vessel ectasia, and focal occlusive lesions in medium-sized vessels, typically in the renal and mesenteric arteries. The reported

**TABLE 90-3** Organ Involvement in Polyarteritis Nodosa

| System | Comment | Frequency | Reference(s) |
|---|---|---|---|
| Constitutional | Fever and weight loss (current and previous) | >90% | 39 |
| Musculoskeletal | Arthritis, arthralgia, myalgia, or weakness; when muscle is involved, it provides a useful site for biopsy | 24%-80% | 19, 27 |
| Skin | Purpura, nodules, livedo reticularis, ulcers, bullous or vesicular eruptions, and segmental skin edema | 44%-50% | 19, 39, 112, 113 |
| Cardiovascular | Cardiac ischemia, cardiomyopathy, hypertension | 35% | 27, 34, 39 |
| Ear, nose, and throat | No involvement; nasal crusting, sinusitis, and hearing loss suggest an alternative diagnosis such as granulomatosis with polyangiitis | None | |
| Respiratory | Lung involvement not seen in PAN; abnormal respiratory findings suggest an alternative diagnosis | None | |
| Abdominal | Pain is an early feature of mesenteric artery involvement; progressive involvement may cause bowel, liver, or splenic infarction, bowel perforation, or bleeding from a ruptured arterial aneurysm; less common presentations include appendicitis, pancreatitis, or cholecystitis as a result of ischemia or infarction; the presence of abdominal tenderness or peritonitis and blood loss on rectal examination should be assessed | 33%-36% | 19, 39 |
| Renal | Vasculitis involving the renal arteries is present in many cases but does not commonly give rise to clinical features; it can present with renal impairment, renal infarcts, or rupture of renal arterial aneurysms; glomerular ischemia may result in mild proteinuria or hematuria, but red cell casts are absent because glomerular inflammation is not a feature; if evidence of glomerular inflammation exists, then an alternative diagnosis such as microscopic polyangiitis or granulomatosis with polyangiitis must be considered; hypertension is a manifestation of renal ischemia causing activation of the renin-angiotensin system | 11%-66% | 19, 39 |
| Nervous system | Mononeuritis multiplex, with sensory symptoms preceding motor deficits; central nervous system involvement is a less frequent finding and can present with encephalopathy, seizures, and stroke | 55%-79% | 19, 39 |
| Ocular | Visual impairment, retinal hemorrhage, and optic ischemia | Rare | 27, 34 |
| Other | Breast or uterine involvement is rare; testicular pain from ischemic orchitis is a characteristic feature, albeit an uncommon presentation | Rare | 114, 115 |

PAN, Polyarteritis nodosa.

sensitivity of conventional angiography is as high as 89% and specificity is 90% when performed in patients suspected of having vasculitis.[42] MR or CT angiography are less invasive alternatives to conventional angiography but are much less sensitive in demonstrating microaneurysms.[43]

MR and CT angiography have the advantage of being able to demonstrate areas of renal infarction and other potential disease. In the setting of high suspicion of PAN and normal CT or MR angiography, it is still necessary to proceed to conventional angiography. Doppler ultrasound can identify renal and hepatic aneurysms related to PAN.[44] A plain chest radiograph may be useful for excluding other diseases such as other vasculitides that may affect the lungs and also to exclude infection.

## Polyarteritis Nodosa in Children

Pediatric cases of polyarteritis have been described, but compared with adult cases, there is less certainty about the case definition. In a careful scrutiny of 110 patients initially labeled as having childhood PAN, with a mean age of 9 years and the male-to-female ratio being equal, only 57% were subsequently classified as having systemic PAN; one-third had cutaneous PAN; 5% had classic PAN associated with hepatitis B surface antigen; and 8% had ANCA$^+$ MPA.[45]

A series of 15 cases of childhood PAN from India[46] described prolonged fever, severe myalgia, skin involvement, and elevated acute phase reactants in all patients. Hypertension (93%) and peripheral neuropathy (46%) were common. Nine patients had peripheral gangrene with ulceration, and six patients had livedo reticularis. No renal, pulmonary, or testicular involvement was present. Skin biopsy specimens showed necrotizing vasculitis of medium-sized vessels.

## Microscopic Polyangiitis Versus Polyarteritis Nodosa

The French Vasculitis Study Group[12] has defined PAN as ANCA$^-$ with a clinical pattern that significantly differs from MPA. A comparison of patients with PAN versus MPA showed a difference in the skin manifestations of the 162 patients with MPA and the 248 patients with PAN.[47] Patients with MPA had a greater frequency of purpura (26%) compared with a frequency of only 19% in patients with PAN. In contrast, urticaria was more common in patients with PAN (6% vs. 1.2%). The presence or absence of HBV infection–influenced skin manifestations were less common (with a rate of only 30%) in HBV$^+$ patients compared with HBV$^-$ patients (54%). Histologic examination of the skin, however, was identical in patients with

**TABLE 90-4** Investigations for Patients with Suspected Polyarteritis Nodosa

| Test | Supports Diagnosis of PAN | Supports an Alternative Diagnosis | Comment |
|---|---|---|---|
| Elevated C-reactive protein | + | | Supports the presence of systemic inflammation, but is nonspecific |
| Elevated ESR | + | | Supports the presence of systemic inflammation, but is nonspecific |
| Elevated serum creatinine | ± | ± | A raised serum creatinine typically without hematuria or proteinuria on urinalysis, may indicate renal ischemia or infarction; significant proteinuria or hematuria (especially red cell casts) would suggest glomerular disease, which is *not* a feature of PAN |
| Abnormal liver function tests | + | | May suggest hepatitis, either from HBV or as a result of ischemic hepatitis from PAN affecting the hepatic arteries |
| Positive HBV serology | + | | Seen in HBV PAN |
| Anemia | + | | Due to chronic inflammation or gastrointestinal blood loss |
| Positive ANCA | | + | A positive ANCA would suggest an alternative type of vasculitis, such as granulomatosis with polyangiitis or MPA |
| Elevated serum creatine kinase | ± | ± | Normal or mildly elevated, despite any muscle involvement |
| Blood cultures | | + | To exclude endocarditis or other infective mimic of vasculitis |
| Positive HCV serology and cryoglobulins | | + | HCV is associated with a skin-limited manifestation of PAN, but typically it is associated with a small-vessel vasculitis related to cryoglobulinemia |
| Positive rheumatoid factor and ACPA | | + | To rule out rheumatoid arthritis, especially in the context of a patient presenting predominantly with arthritis |
| Positive ANA and anti-dsDNA | | + | In patients with clinical features consistent with SLE or other connective tissue disease |
| HIV positive | | + | |

ACPA, Anti-citrullinated protein antibody; ANA, anti-nuclear antibody; ANCA, anti-neutrophil cytoplasmic antibody; dsDNA, double-stranded DNA; ESR, erythrocyte sedimentation rate; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; MPA, microscopic polyangiitis; PAN, polyarteritis nodosa; SLE, systemic lupus erythematosus.

Modified from Mukhtyar C, Guillevin L, Cid MC, et al: EULAR recommendations for management of primary small and medium vessel vasculitis. *Ann Rheum Dis* 68:310–317, 2009.

either MPA or PAN (see Chapter 89 for more details on MPA).

## Cutaneous Polyarteritis Nodosa

Cutaneous PAN is a localized chronic arteritis affecting small arteries and/or arterioles in the panniculus (medium vessels) and in the dermo-subcutaneous junction. Arteritis may or may not be present in adjacent skeletal muscle and peripheral nerves, but the condition only rarely affects small arteries or arterioles in the dermis and does not affect venules at all. Because it can also involve vessels of the muscles and nerves under the involved skin,[48] use of the term "limb-restricted vasculitis" has been recommended, but this term would not account for a few patients who have manifestations of the disease on the trunk. Unlike systemic PAN, cutaneous PAN is usually a more chronic disease. Because of the involvement of small arteries and/or arterioles,[49] the characteristic clinical features are livedo (i.e., an irregular asymmetric pattern of so-called "broken livedo" or "livedo racemosa"; Figure 90-2) and small intradermal nodules with or without ulcers (Figure 90-3). If the disease involves vessels in the local muscle and epineurium, the patients may experience neuropathy and pain. Cutaneous PAN is perhaps a misnomer because it might suggest that

**Figure 90-3** Cutaneous ulceration and livedo in a patient with cutaneous polyarteritis nodosa. *(Courtesy Professor Sunderkoetter, Department of Dermatology, University Hospital of Muenster.)*

the disease can become more widespread; however, good-quality evidence indicates that cutaneous PAN does not progress into classic or systemic PAN.[49-55]

Pathologically, the findings of a skin biopsy are indistinguishable between systemic PAN and cutaneous PAN,[35] but the absence of venule involvement in cutaneous PAN is an important distinction. In a retrospective review of patients with cutaneous PAN from a Japanese group, 22 patients with histologically proven cutaneous vasculitis underwent follow-up: 32% had a peripheral neuropathy and 27% had myalgia, suggesting a need to revise the current criteria to differentiate between the two entities of cutaneous PAN and PAN. It was suggested that the two conditions were indeed separate, but cutaneous PAN is not confined to the skin.[48] HCV infection has been associated with cutaneous PAN in one retrospective study of 16 patients, in which 5 individuals had HCV infection.[56]

## Hepatitis B Virus Polyarteritis Nodosa

Hepatitis B vasculitis occurs in people with chronic hepatitis B antigenemia, most of whom have active liver disease.[24] The manifestations vary considerably, from diffuse small-vessel vasculitis predominantly in the skin to lesions in larger vessels, as is typical of PAN. Clinical symptoms may include the entire spectrum of vasculitic manifestations, from purpura and other rashes to abdominal pain, hypertension, renal disease, and stroke. HBV-associated PAN is an increasingly rare condition as a result of better immunization programs against hepatitis B. A cohort of 115 patients with PAN was reviewed on the basis of inclusion into studies between 1972 and 2002.[27] Treatment of hepatitis B–related PAN with steroids plus an anti-viral agent plus plasmapheresis resulted in 81% of patients achieving remission and a subsequent 10% relapse rate. However, 36% subsequently died. Seroconversion of hepatitis B antibody status was associated with complete remission and no relapse. In patients with a negative ANCA test the major cause of death was gut involvement. Plasmapheresis not only achieved control of disease in combination with steroids and anti-viral therapy but facilitated seroconversion to prevent secondary long-term complications from HBV infections such as liver involvement.

## Non–Hepatitis B Virus Polyarteritis Nodosa

The French Vasculitis Study Group has combined data on PAN and MIP, focusing more on the severity of disease manifestations rather than on the type of disease in their studies of treatment or outcome. For example, Ribi and colleagues[57] described the outcome of 124 patients with a new diagnosis of either PAN or MPA in whom the outcome was likely to be good (based on a lack of poor prognostic factors as measured by the Five-Factor Score). All patients were treated with corticosteroids, followed by either azathioprine or cyclophosphamide only if they experienced a relapse. Ninety-eight of these patients achieved remission with steroids alone, but 46 of these patients had a relapse. Primary treatment with steroids failed to control the disease in 26 patients, and 49 of the original 124 patients required additional immunosuppression. Similar rates of improvement were documented by using either azathioprine or cyclophosphamide. Therefore, despite the absence of poor prognostic factors, the disease of only approximately 50% of patients could be managed with corticosteroids alone. A study of plasma exchange in 62 patients with a mixture of EGPA and what was described as PAN suggested that no clinical benefit was achieved from adding plasma exchange to standard treatment with pulse intermittent high-dose cyclophosphamide and steroid. This study from the mid-1990s describes patients with "PAN," but most of these patients probably had MPA.[58] Table 90-5 lists treatment regimens for non-HBV PAN that are based on the European League against Rheumatism guidelines on management of small- and medium-vessel vasculitis.[59]

Management of non-HBV PAN should be appropriate to the severity of the disease as defined by the prognostic Five-Factor Score and includes aggressive immunosuppression with corticosteroids and cyclophosphamide in patients with Five-Factor Score values of at least 1.[62]

## Outcome

Uncontrolled vasculitis accounts for 58% to 73% of deaths occurring within the first year of diagnosis.[60-62] Earlier diagnosis and initiation of treatment has improved outcomes. In non-HBV PAN, the 7-year survival rate is 79%, compared with a 5-year survival rate of 72.5% in HBV-related PAN. These rates are similar to the rates in patients who have vasculitis associated with ANCAs.[63] The relapse rate in patients with HBV-related PAN is low (<10%) compared with that in people with non–HBV-related PAN (relapse rates of 19.4% to 57%).[27,62] Delayed diagnosis (>3 months) increases the risk of relapse but does not affect mortality risk.[64] Seroconversion rates from hepatitis B e-antigen

**TABLE 90-5** Pulse Cyclophosphamide and Methylprednisolone for Non–Hepatitis B Virus Polyarteritis Nodosa

| Phase | Drug | Dose | Route | Frequency | Duration |
|---|---|---|---|---|---|
| Induction | Cyclophosphamide | 15 mg/kg per pulse | IV | Every 2 weeks × 3, then every 3 weeks × 3-6 | 3-6 months |
| Induction | Prednisolone | 1 mg/kg up to 60 mg/day | Oral | For 4 weeks then reduce to 15 mg/day by 3 months, then further reduce to 10 mg/day by 6 months | 6 months |
| Maintenance | Azathioprine | 2 mg/kg/day | Oral | Daily | 18-24 months, then stop |
| Maintenance | Prednisone | 7.5 mg/day | Oral | Daily | 18-24 months, then reduce |

IV, Intravenous.

positive to hepatitis B e-antibody positive (i.e., eradication of active viral infection) is achieved in almost 50% of patients treated with glucocorticoids and anti-viral agents plus limited plasmapheresis.[27]

A prognostic tool designed for use in people with PAN is effectively used to distinguish patients with higher or lower risk of poor outcome. This simple clinical score (the Five-Factor Score), assessed at diagnosis, consists of assessment of the following abnormalities: proteinuria (<1 g/day), elevated creatinine (>1.58 mg/dL), gastrointestinal involvement, central nervous system involvement, and cardiomyopathy.[65] One point per item is allocated. Survival is reduced for patients with higher scores (86% survival for 0 points, 69% survival for 1 point, and 47% survival for 2 or more points) at onset when patients are followed up for 6 years.[65] Mortality can also be predicted using the Birmingham Vasculitis Activity Score, a clinical index of disease activity.[40,62] Older age at diagnosis is an important adverse predictor of survival in the first year and after 5 years of follow-up.[60,66]

A recent study of 118 patients[67] with PAN or MPA who have a good prognosis (Five-Factor Score = 0) has shown that after more than 8 years of follow-up, the mortality rates are better than for GPA (93% at 5 years and 86% at 8 years), based on treatment with glucocorticoids alone in 88% of patients; additional immunosuppression was required in 18% of patients, rising to 47% during follow-up.

## COGAN'S SYNDROME

Cogan's syndrome[68] is a rare form of vasculitis. The median age at onset is 25 years.[69,70] Patients typically present with red painful eyes and/or hearing loss concurrently or within 4 months in 75% of patients. Features of more widespread systemic vasculitis do not develop in most patients, with the exception of aortitis and aneurysm or aortic insufficiency, which occurs in about 12% of patients.[71] With atypical Cogan's syndrome, in which the ocular manifestation is episcleritis, scleritis, iritis, uveitis, or chorioretinitis rather than interstitial keratitis, there is a worse prognosis and a higher frequency of aortic and other systemic manifestations.[72] Eye symptoms usually consist of photophobia with red and irritable eyes. The audiovestibular symptoms are rapid in onset with partial or complete hearing loss (often bilateral), vertigo, and ataxia. Although the vertigo and ataxia may improve, the hearing loss is usually permanent. In about 50% of cases, constitutional features will be present, such as weight loss, fever, lymphadenopathy, hepatosplenomegaly, and purpura. Aortic involvement is the most serious manifestation of Cogan's syndrome and accounts for most deaths. Ophthalmic and audiovestibular features may precede aortic involvement by months to several years. Rarely, widespread vasculitis develops, with purpura and gangrene.[73]

### Pathology

A mixture of acute and chronic inflammation is present in large blood vessels, especially around the internal elastic lamina. The main findings are an infiltration of neutrophils, eosinophils, mononuclear cells, and fibrosis. Occasionally, granulomas containing giant cells can be found in the lesions.

### Clinical Features

The diagnosis of Cogan's syndrome is largely based on clinical features, supported by histologic abnormalities and exclusion of other conditions. Definitive serologic markers do not exist. Most patients have leukocytosis, anemia, thrombocytosis, and an elevated sedimentation rate during active phases of their disease. Patients with aortitis show aortic root dilation and aortic insufficiency on echocardiography or MR imaging. Rare case reports demonstrate the presence of autoantibodies such as anti-endothelial cell antibodies[74] and anti-myeloperoxidase (MPO) antibodies,[75] but their role in the disease is unknown. Recent reports suggest that antibodies to heat shock protein (HSP70) are very commonly found (in more than 90% of cases) in patients with typical Cogan's syndrome, but these antibodies are much less common (17%) in atypical forms.[76]

### Treatment

No clear evidence base exists because no prospective studies of treatment have been performed in people with this rare disease. Interstitial keratitis usually responds to topical corticosteroids. Most experts manage the acute audiovestibular symptoms with high doses of glucocorticoids, with a prompt response within a month (or none at all in resistant cases). Cytotoxic drugs,[77] methotrexate,[78] and cyclosporine[79] have been used to treat the condition. The course is variable: Some patients have only a single episode and are free of active disease thereafter. The more typical course is one of waxing and waning symptoms for months or years. Most patients sustain permanent hearing loss, and almost half lose their hearing entirely; by contrast, few experience permanent vision-related effects.[71]

Cochlear implantation can successfully restore some hearing in these patients. Aortic valve replacement and surgical repair of aortic aneurysms may be required, but as in Takayasu's arteritis,[80] it would probably be best to ensure that there is no active disease at the time of surgery.

## BUERGER'S DISEASE

Buerger's disease, also known as *thromboangiitis obliterans*, is an inflammatory vaso-occlusive disease that predominantly affects the vascular supply to the lower limbs in young adult male tobacco smokers, although women and older adults[81] can also be affected. The average age at onset is 35 years. Tobacco, especially cigarette smoking, is clearly important, but the mechanism of action remains unknown. There is no clear human leukocyte antigen association.[82] Antibodies directed against collagen, elastin, and laminin have been reported in some patients.[83,84] The presence of high levels of anti-endothelial cell antibodies has been described in patients with active disease, but not in patients in remission.[85] ANCAs directed against MPO, lactoferrin, and elastase have also been associated with severe cases.[86] More recently, a link to periodontal disease and anti-cardiolipin antibody has been reported.[87]

### Pathology

In most cases Buerger's disease affects small arteries and veins in the distal extremities, but some case reports describe visceral arterial involvement, including coronary, pulmonary, and mesenteric arteries. A transmural infiltration of polymorphonuclear leukocytes and lymphocytes occurs with preservation of the internal elastic lamina.[88] Thrombosis is prominent, and microabscesses can be found in the vessel wall and surrounding tissue. The infiltrating cells are enriched in $CD3^+$ T cells, and $CD68^+$ macrophages and dendritic cells have been reported to be increased during disease activity.[89]

### Clinical Features

Buerger's disease typically begins with bilateral pain and ischemia in both lower extremities, although the upper extremities may be the site of initial symptoms. At first the symptoms can be mild, with paresthesia or pain upon exposure to cold. Most cases evolve rapidly, however, with increasing ischemic (claudicant) limb pain, digital cyanosis, splinter hemorrhages, and skin vesicles. Digital ulcers often occur, especially after minor trauma.[90] The disease typically begins distally, with symptoms worse in the tips of the toes (and fingers), but it progresses to larger, more proximal vessels over several years. Usually Buerger's disease does not cause proximal leg claudication. Superficial phlebitis occurs in about one-third of patients and may be the first symptom. Typical angiographic changes include multiple bilateral areas of narrowing or occlusion in the digital, palmar, plantar, ulnar, radial, tibial, and peroneal arteries. Small collateral vessels around the occlusion can appear to be corkscrew shaped. More proximal lesions resemble atherosclerotic occlusion. Although these findings are typical, none is pathognomonic; in the absence of pathologic confirmation, the differential diagnosis includes premature atherosclerosis; hyperviscosity syndrome; scleroderma and other rheumatic diseases; Takayasu's arteritis; embolic disease including cholesterol emboli and atrial myxomas; ergot toxicity; and thoracic outlet syndrome.

### Treatment

The most important aspect of treatment is to stop smoking. In patients who are unable to comply, nicotine substitutes may be used at least in the short term.[91]

Affected limbs must be protected from trauma and cold. Ulcers and cellulitis often require antibiotics and local wound management. Anecdotal use of calcium channel blockers and pentoxifylline reportedly has been beneficial in some, but not all, patients. Sympathectomy seems to provide little or no long-term benefit and is not usually recommended.[92] Intravenous prostacyclin is effective[93] and superior to aspirin[94] and is also superior to lumbar sympathectomy for rest pain or ischemic ulcers[92] on the basis of two large randomized controlled trials. Combining smoking cessation with intravenous prostacyclin has been effective in an open-label study of 13 cases.[95] Other approaches using bone marrow–derived mesenchymal stem cells, basic fibroblast growth factor, and granulocyte colony-stimulating factor have been effective in treatment of leg ulcers and ischemia in small open-label studies.[96-99] A series of 26 patients with Buerger's disease responded well to autologous bone marrow mononuclear cell transplantation, with a subsequent increase in the 4-year amputation-free rate from 6% in 16 untreated control subjects to 95% in treated cases.[100] Hepatocyte growth factor has been effective in a series of 22 patients with peripheral vascular disease, of whom 8 were classified as having Buerger's disease.[101]

A radical surgical approach using omental grafting is reported in large open-label surgical studies to offer more than 90% success in improving the severe ischemic complications.[102]

In patients who continue to smoke, about half require amputation, often multiple times as more proximal vessels are involved.[103] Most patients who stop smoking will stop getting worse, but a few still require amputation. However, the ischemic limb may be a source of pain and ulceration for many years.

## SUSAC'S SYNDROME

Susac's syndrome is another rare condition affecting a wide age range from children to older adults.[104-106]

The cause of this syndrome is unknown. The presentation is usually characterized by sudden onset of sensorineural hearing loss in the context of encephalopathy and branch retinal artery occlusion.[104]

The differential diagnosis includes Cogan's syndrome and GPA. The pathogenetic mechanisms suggest an endotheliopathy rather than a true vasculitis. Nevertheless, treatment with immunosuppressive agents, including glucocorticoids and cytotoxic agents, is reported to lead to improvement in some patients, but no controlled trials have been performed.[105] The diagnosis rests on the combination of clinical features and exclusion of other causes. The outcome is variable, but most patients recover some hearing.[107] Anti-endothelial cell antibodies have recently been reported in association with the disease.[108]

## VIRUS-INDUCED VASCULITIS

The most common virus-associated vasculitis today is HCV-associated cryoglobulinemia (see Chapter 91). The majority of patients with cryoglobulinemia have concomitant hepatitis C infection (see Chapter 91). Treatment with immunosuppressive drugs has been only moderately successful, and many patients die as a result of vasculitis or liver disease. Saadoun and colleagues[29] describe a cohort of 72 patients treated with combination anti-viral therapy. Patients responded well to a combination of interferon-$\alpha$ and ribavirin; however, 40% required glucocorticoids, approximately 12% had plasmapheresis, and 6% received immunosuppressive drugs for severe complications. The mortality was just over 10%. The vasculitis resulting from human immunodeficiency virus infection is discussed in Chapter 113. Although the most common rheumatic manifestation of parvovirus B19 infection is arthritis (see Chapter 114), in some children with chronic parvovirus B19 infection, a vasculitis similar to PAN has been reported to develop. Given the high incidence of the infection in children, it is not clear whether the presence of the virus is coincidental or causative in the few cases of vasculitis described.[109]

## INFECTIONS AND VASCULITIS

Much speculation still exists about the relationship between a number of other organisms and the development of vasculitis. Has the organism been directly responsible for inducing vasculitis, or did it merely act as a trigger? Is the presence of the organism or evidence of its recent or previous presence sufficient evidence to indicate that it played a key role in the onset or propagation of the disease? Did the vasculitis or its treatment change the tissue architecture, suppress immune responses, and increase the likelihood of secondary infection? A variant of a common soil organism *Burkholderia pseudomallei* (which in itself causes melioidosis) has been found in arterial biopsies from a small series of patients with giant cell arteritis.[110] Furthermore, serologic evidence of the organism's lipopolysaccharide was detected at high levels in a larger series of 61 patients with GCA, but not in any of the 102 control subjects. Therefore, with few exceptions, as discussed earlier in this chapter, the link between vasculitis and infection remains tenuous.[111]

CHAPTER 91

# Immune Complex–Mediated Small-Vessel Vasculitis

John H. Stone

**KEY POINTS**

- Vasculitis mediated by immune complexes (ICs) includes a heterogeneous group of disorders linked by inefficient or dysregulated IC clearance.
- Cutaneous involvement of small blood vessels is the most prominent feature in most cases, but extracutaneous involvement occurs in some forms.
- The classic cutaneous finding in small-vessel vasculitis is palpable purpura, but a variety of other skin lesions may be found, including pustules, vesicles, urticaria, and small ulcerations.
- Direct immunofluorescence studies of involved blood vessels demonstrate characteristic types and patterns of immunoglobulin (Ig) and complement deposition.
- The most common types of IC-mediated vasculitis are hypersensitivity vasculitis, Henoch-Schönlein purpura, and mixed cryoglobulinemia. Rarer types include hypocomplementemic urticarial vasculitis and erythema elevatum diutinum.
- Hypersensitivity vasculitis most often results from a reaction to a medication or an infection.
- IgA vasculitis (Henoch-Schönlein purpura) is associated with purpura, arthritis, glomerulonephritis, and colicky abdominal pain. IgA deposition is found within blood vessel walls.
- Cryoglobulinemic vasculitis is most often associated with long-standing hepatitis C virus infection. The term *mixed cryoglobulinemia* is sometimes used for this disorder because the immunoreactants involved in the disease include both IgG and IgM.
- Other immune-mediated disorders such as systemic lupus erythematosus, Sjögren's syndrome, and rheumatoid arthritis can be associated with IC-mediated vasculitis.

The inflammation within blood vessel walls that characterizes vasculitis frequently leads to cellular destruction, damage to the vascular structures, compromised blood flow to organs, and organ dysfunction. It has been known for decades that immune complex (IC)–mediated mechanisms play critical roles in many forms of systemic vasculitis, particularly those that primarily involve small blood vessels. The use of horse serum and sulfonamides as therapeutic agents for infectious diseases in the early 1900s frequently led to small-vessel vasculitis as a result of serum sickness or hypersensitivity phenomena. *Hypersensitivity angiitis*, which is often confused with the pauci-immune form of vasculitis now called *microscopic polyangiitis* (see Chapter 87)[1,2] was one of five disorders included in the original classification of the vasculitides by Zeek in 1952.[3]

This chapter focuses on forms of small-vessel vasculitis that are mediated by IC deposition. These disorders include hypersensitivity vasculitis, immunoglobulin (Ig) A vasculitis/Henoch-Schönlein purpura (HSP), mixed cryoglobulinemia, hypocomplementemic urticarial vasculitis (UV), and erythema elevatum diutinum (EED). In addition, forms of vasculitis associated with connective tissue diseases (CTDs), particularly systemic lupus erythematosus (SLE), Sjögren's syndrome, and rheumatoid vasculitis (RV), are discussed briefly. Antiglomerular basement membrane disease and the pauci-immune forms of vasculitis such as those associated with anti-neutrophil cytoplasmic antibodies (ANCAs) are discussed in Chapter 89. Throughout this chapter, the terms *vasculitis* and *angiitis* are used interchangeably when referring to inflammation involving small blood vessels (i.e., capillaries, venules, and arterioles).

Because all forms of IC-mediated vasculitis share certain elements of pathogenesis, have many cutaneous findings in common, and have overlapping differential diagnoses, these aspects of the disorders are considered together. The epidemiology, cause, distinctive pathophysiologic mechanisms, unique clinical features, and approaches to treatment are discussed separately for each condition. Treatments are also summarized in Table 91-1.

## PATHOGENESIS

### Arthus Reaction

The Arthus reaction, described on the basis of clinical and histologic findings after the injection of horse serum into rabbits, forms the basis of our understanding of IC-mediated diseases.[4] The formation of ICs in the Arthus reaction initiates complement activation and an influx of inflammatory cells, followed by thrombus formation and hemorrhagic infarction in the areas of most intense inflammation. ICs, formed by the combination of antibody and antigen, are continuously created by the reticuloendothelial system as a means of neutralizing foreign antigens, but ICs are usually cleared swiftly and efficiently. Under some circumstances, however, ICs escape clearance and are deposited within joints, blood vessels, and other tissues, inciting inflammation and causing disease. Deposition of ICs in the blood vessel walls leads to vasculitis. Similarly, deposition of ICs within small blood vessels of the kidney—the glomeruli—causes glomerulonephritis.[5]

**TABLE 91-1** Potential Treatment Approaches for Different Forms of Immune Complex–Mediated Vasculitis

| Disease | Preferred Treatment Approach |
|---|---|
| Hypersensitivity vasculitis | Remove the offending agent<br>Brief (2- to 4-wk) course of glucocorticoids for severe cases |
| Immunoglobulin A vasculitis/Henoch-Schönlein purpura | No treatment required in the majority of cases, particularly in children (symptomatic therapy only)<br>Moderate glucocorticoid doses (prednisone, 20-40 mg/day) are of variable utility but may be used empirically in patients with disabling symptoms<br>Pulse glucocorticoids (e.g., 1 g methylprednisolone/day) have been used with anecdotal success for refractory purpura when moderate glucocorticoid doses have failed<br>Refractory glomerulonephritis may require high-dose glucocorticoids; mycophenolate mofetil is preferred as a steroid-sparing agent or when additional immunosuppression is required |
| Cryoglobulinemia | Combined anti-viral therapies and B cell depletion strategies are synergistic in treating mixed cryoglobulinemia associated with hepatitis C<br>Rituximab is possibly effective in treating idiopathic mixed cryoglobulinemia |
| Hypocomplementemic urticarial vasculitis | Low-dose prednisone (5-20 mg/day), hydroxychloroquine, dapsone<br>Higher doses of glucocorticoids in patients with serious internal organ involvement or ulcerative skin lesions<br>Anecdotal reports of success with tumor necrosis factor inhibition |
| Erythema elevatum diutinum | Dapsone or sulfapyridine |
| Connective tissue disease | Hydroxychloroquine, low-dose prednisone (5-20 mg/day), azathioprine |
| Rheumatoid vasculitis | High-dose glucocorticoids plus rituximab is an appropriate first choice for widespread necrotizing vasculitis, adding rituximab within several weeks if evidence of treatment failure is seen<br>Tumor necrosis factor inhibition may also be useful in milder cases |

## Immunogenicity

The fate of ICs formed by the reticuloendothelial system is governed by several major factors, including antigen load, antibody response, efficiency of the reticuloendothelial system, the flow dynamics of blood vessels, previous endothelial damage, and the solubility of the ICs themselves. The ratio of antibody to antigen determines the solubility of ICs. Large ICs, which are formed when antibody and antigen are present in approximately equal proportions, are identified and removed easily by the reticuloendothelial system. Smaller ICs are formed in conditions of antibody excess. These complexes remain in the serum and do not elicit an immune response within tissues. In the setting of slight antigen excess, however, ICs precipitate from the serum and become trapped within certain vascular beds. After the deposition of ICs in tissue, a cascade of pathologic events ensues: complement fixation, neutrophil recruitment, local inflammation, lysosomal release, oxygen free radical generation, and tissue injury.

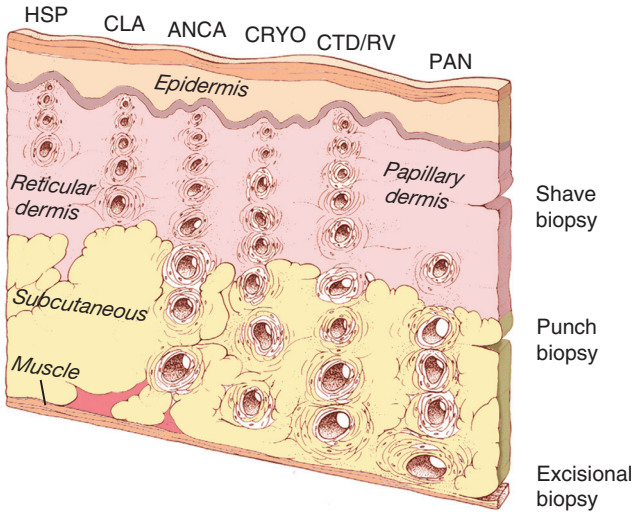

**Figure 91-1** Size of the blood vessels involved in forms of cutaneous vasculitis. The types of vasculitis with an immune complex–mediated pathogenesis include Henoch-Schönlein purpura (HSP), cutaneous leukocytoclastic angiitis (CLA), mixed cryoglobulinemia (CRYO), and connective tissue disease/rheumatoid vasculitis (CTD/RV). ANCA, Antineutrophil cytoplasmic antibody; PAN, polyarteritis nodosa.

## CUTANEOUS MANIFESTATIONS

Small blood vessels generally include capillaries, postcapillary venules, and nonmuscular arterioles—that is, vessels typically less than 50 μm in diameter. These vessels are found principally within the superficial papillary dermis (Figure 91-1). Medium-sized blood vessels—those between 50 and 150 μm in diameter—contain muscular walls and are located principally in the deep reticular dermis, near the junction of the dermis and subcutaneous tissues. Vessels larger than 150 μm in diameter are not commonly found in the skin.

Figure 91-1, which demonstrates the location and size of blood vessels involved in various types of cutaneous vasculitis, illustrates the types of blood vessels affected by several forms of IC-mediated disease. The size of a blood vessel correlates closely with its depth in the skin layers—the larger the vessel, the deeper its location. Although telltale signs of vasculitis may be evident upon inspection of the skin's surface, the epidermis is avascular. Therefore, the pathologic findings in cutaneous vasculitides lie within the dermis and subcutaneous tissues.

Palpable purpura, which is essentially pathognomonic for small-vessel vasculitis, is the most common cutaneous finding in IC-mediated vasculitis (Figure 91-2). Purpuric lesions result from the extravasation of erythrocytes through damaged blood vessel walls into tissue. Many other skin

manifestations are possible in these conditions, including vesicles, pustules, urticaria, superficial ulcerations, nonpalpable lesions (macules and patches), and splinter hemorrhages (Figure 91-3). These lesions frequently occur in combination, and careful examination usually reveals a purpuric component. Purpuric lesions *do not blanch* when pressure is applied to the skin, and they are slightly raised. After resolution, purpuric lesions may leave postinflammatory hyperpigmentation, particularly if repeated bouts occur (see Figure 91-3F).

**Figure 91-2** Palpable purpura in a patient with hypersensitivity vasculitis.

In IC-mediated vasculitis, purpuric lesions are usually distributed in a symmetric fashion over dependent regions of the body, particularly the lower legs, because of the increased hydrostatic pressure in these areas. Purpuric lesions are not always palpable, and the existence of palpable purpura does not necessarily imply an IC-mediated pathophysiology; pauci-immune forms of vasculitis such as granulomatosis with polyangiitis (GPA), microscopic polyangiitis, and eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome), for example, may present with similar findings in the skin (albeit with distinctive histopathology; see Chapter 89), including either palpable or nonpalpable purpura. In contrast to pauci-immune forms of vasculitis, however, which usually lead to small, circumscribed areas of cutaneous vasculitis, cutaneous vasculitis associated with ICs often leads to diffuse, widespread lesions, usually occurring most densely on the distal lower extremities but extending up the thighs to the buttocks, abdomen, trunk, upper extremities, and occasionally even the face.

## HISTOPATHOLOGY

Full pathologic assessment of cutaneous vasculitis involves examination of a skin biopsy specimen by both light

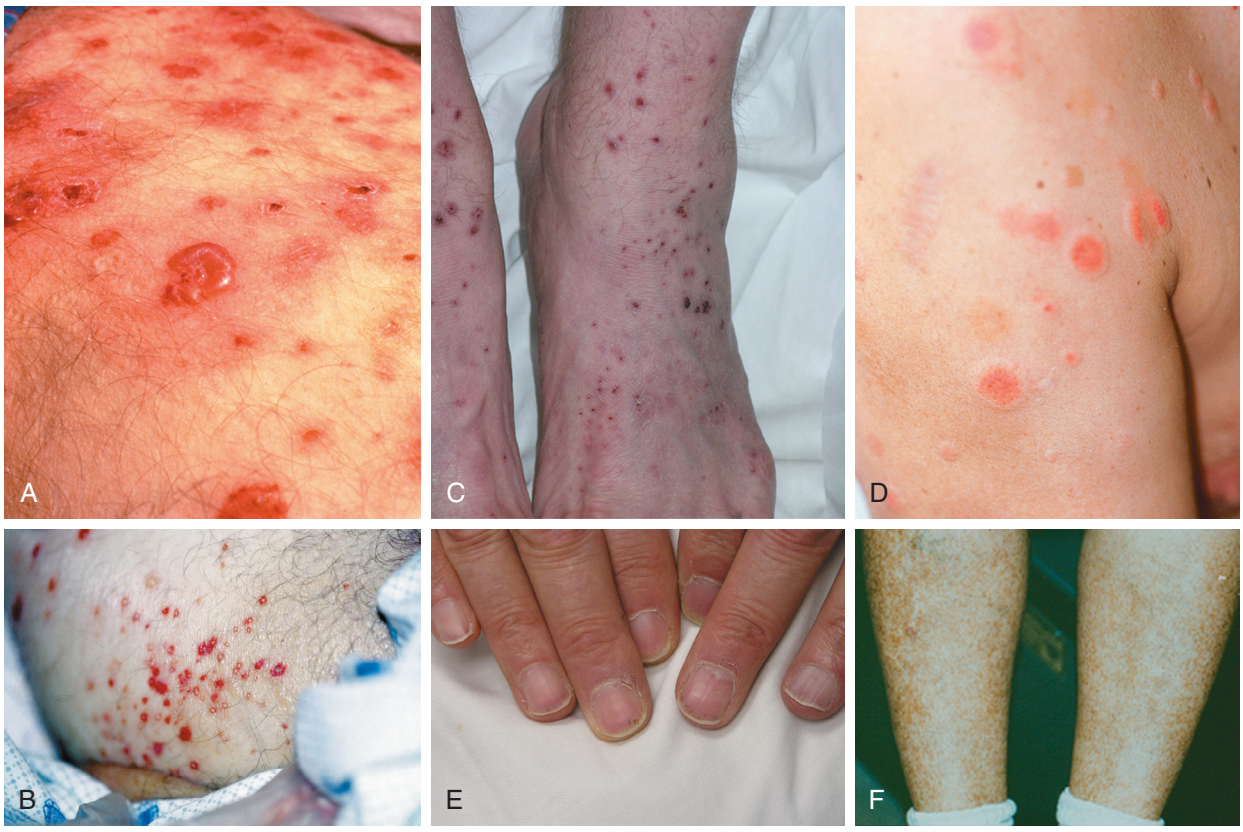

**Figure 91-3** Cutaneous findings of immune complex–mediated small-vessel vasculitis. **A,** Vesicles. **B,** Pustules. **C,** Superficial ulcerations. **D,** Urticaria. **E,** Splinter hemorrhages. **F,** Hyperpigmentation.

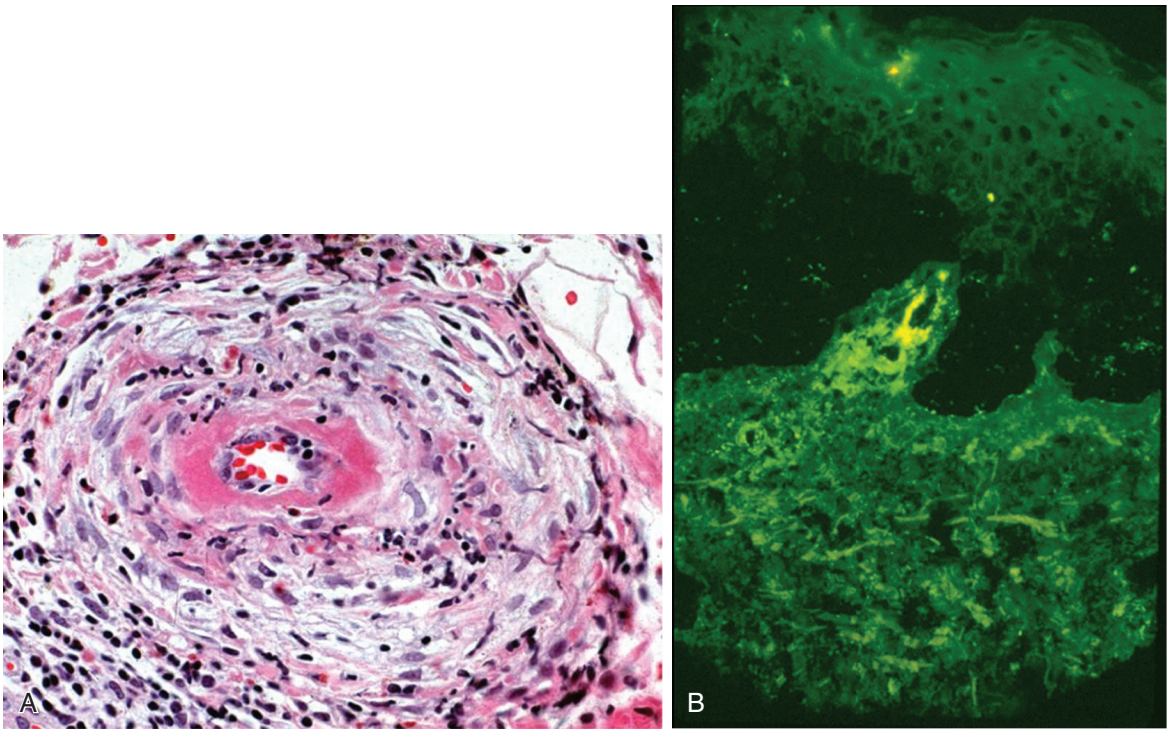

**Figure 91-4** Skin biopsy findings in immune complex–mediated small-vessel vasculitis. **A,** Light microscopy. **B,** Direct immunofluorescence demonstrating immunoglobulin A deposits. See text for description of the key features.

microscopy and direct immunofluorescence (DIF). DIF is a particularly critical procedure in the evaluation of small-vessel vasculitides. DIF studies must be planned at the time the biopsy is performed because they require a fresh skin biopsy sample.

## Light Microscopy

Figure 91-4A displays the light microscopy findings of cutaneous vasculitis. The optimal time for skin biopsy is 24 to 48 hours after the appearance of a lesion. Biopsies should be obtained from a non-ulcerated site. For ulcerated lesions—which are usually more of an issue with medium-vessel vasculitides—biopsy specimens should be taken from the edge of the ulcer. The cellular infiltrates in cutaneous vasculitis are usually composed of a combination of neutrophils and lymphocytes, but most cases demonstrate a predominance of one cell type or the other. Lymphocyte-rich infiltrates may be seen in specimens taken from either new lesions (those present <12 hours) or old lesions (those present >48 hours), regardless of the underlying type of vasculitis. Even in CTDs such as Sjögren's syndrome, the typical finding is a leukocytoclastic vasculitis rather than a lymphocytic vasculitis.[6]

The essential histologic feature in any form of cutaneous vasculitis is the disruption of blood vessel architecture by an inflammatory infiltrate within and around the vessel walls. Endothelial swelling and proliferation, leukocytoclasis (i.e., degranulation of neutrophils, leading to the production of nuclear "dust" due to apoptosis; see Figure 91-4), and extravasation of erythrocytes may be evident in the biopsy but are not essential to the diagnosis.

## Direct Immunofluorescence

Although the diagnosis of cutaneous vasculitis rests on routine histologic findings, the features revealed by hematoxylin and eosin stains do not distinguish between pauci-immune and IC-mediated disorders. DIF studies complement the histologic information, provide the only way of diagnosing HSP with certainty, and yield important clues regarding the nature of the underlying disease. The performance of *separate* biopsies for histologic and DIF analyses is recommended if sufficient numbers of lesions exist (as is usually the case with IC-mediated vasculitis).

To perform DIF studies, frozen sections are incubated with fluorescein-labeled anti-human IgG, IgM, IgA, and C3. The staining patterns of these immunoreactants may provide insight into not only the diagnosis but also the pathophysiology of certain conditions. Figure 91-4B displays the typical DIF findings in a skin lesion from a patient with IC-mediated vasculitis.

# DIFFERENTIAL DIAGNOSIS

The differential diagnosis of IC-mediated small-vessel vasculitis is shown in Table 91-2. The following three main groups of disorders are present in the differential diagnosis of IC-mediated small-vessel vasculitis:

- Other forms of IC-mediated disorders
- Forms of small-vessel vasculitis that are not mediated through ICs
- Vasculitis mimickers that involve small blood vessels

A diagnostic algorithm that includes the critical laboratory and radiographic tests is shown in Figure 91-5.

**TABLE 91-2** Differential Diagnosis of Immune Complex–Mediated Vasculitis

| |
|---|
| **Immune Complex–Mediated Vasculitides** |
| Hypersensitivity vasculitis |
| Henoch-Schönlein purpura |
| Mixed cryoglobulinemia |
| Urticarial vasculitis |
| Erythema elevatum diutinum |
| Connective tissue disease, rheumatoid vasculitis |
| **Pauci-immune Vasculitides** |
| Granulomatosis with polyangiitis |
| Eosinophilic granulomatosis with polyangiitis |
| Microscopic polyangiitis |
| **Miscellaneous Small-Vessel Vasculitides** |
| Behçet's disease |
| Malignancy associated |
| Infection |
| Inflammatory bowel disease |
| **Vasculitis Mimickers** |
| Hemorrhage |
| • Pigmented purpuric dermatoses |
| • Scurvy |
| • Immune thrombocytopenic purpura |
| Thrombosis |
| • Anti-phospholipid syndrome |
| • Thrombotic thrombocytopenic purpura |
| • Livedoid vasculopathy (atrophie blanche) |
| • Warfarin-induced skin necrosis |
| • Purpura fulminans |
| • Disseminated intravascular coagulation |
| Embolism |
| • Cholesterol emboli |
| • Atrial myxoma |
| Vascular wall pathology |
| • Calciphylaxis |
| • Amyloidosis |
| Infection |
| • Infective endocarditis |
| • Leprosy (Lucio's phenomenon) |

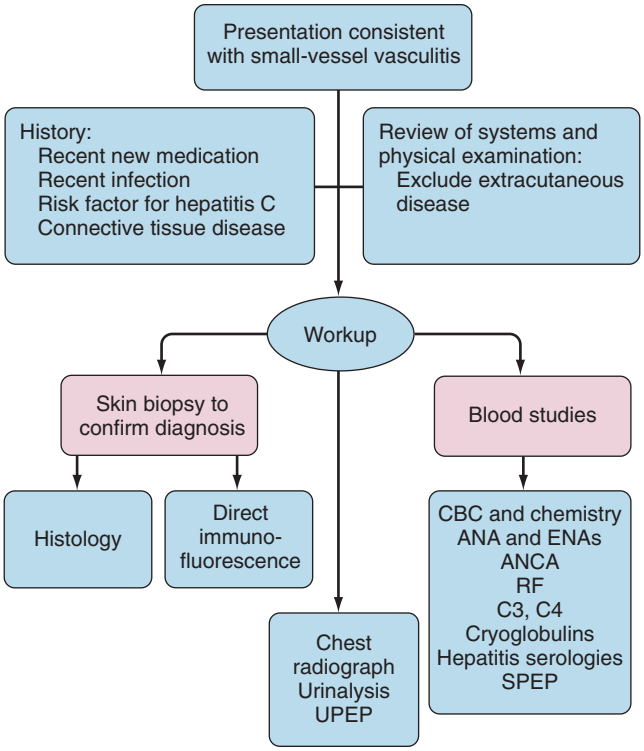

**Figure 91-5** Diagnostic algorithm for immune complex–mediated small-vessel vasculitis. The critical diagnostic test is usually a skin biopsy with hematoxylin and eosin staining and direct immunofluorescence. ANA, Anti-nuclear antibody; ANCA, anti-neutrophil cytoplasmic antibody; CBC, complete blood cell count; ENA, extractable nuclear antigen; RF, rheumatoid factor; SPEP, serum protein electrophoresis; UPEP, urine protein electrophoresis.

## CLINICAL SYNDROMES

### Hypersensitivity Vasculitis

The term *hypersensitivity vasculitis* (see Chapter 87) generally refers to an IC-mediated small-vessel vasculitis of the skin that spares internal organs and usually follows drug exposures or infections. Consensus conference meetings on the nomenclature of the vasculitides have grappled with the most appropriate way to address the terminology for hypersensitivity vasculitis, a term first used by Zeek in 1952. The first Chapel Hill Consensus Conference in the early 1990s recommended eliminating the term *hypersensitivity vasculitis* in favor of *cutaneous leukocytoclastic angiitis* because of the disorder's usual confinement to the skin and its predominant cell type, the neutrophil.[1]

Twenty years later, the second Chapel Hill Consensus Conference retained the term "cutaneous leukocytoclastic angiitis" under a newly created category of *Single-Organ Vasculitis*, consistent with the idea that hypersensitivity has a predilection for the skin. That same conference also added a new nomenclature term—"drug-induced immune complex vasculitis"—under a new category, *vasculitis associated with probable etiology*. The concept of hypersensitivity vasculitis, a condition characterized pathologically by IC deposition in capillaries, postcapillary venules, and arterioles, remains firmly embedded in the medical literature and clearly encompasses both cutaneous leukocytoclastic angiitis and drug-induced immune complex vasculitis. Because pathophysiology and treatment of these hypersensitivity vasculitis subsets are similar, it makes sense to consider them together. An illness that is similar to hypersensitivity vasculitis—serum sickness—is a systemic illness that includes not only cutaneous involvement but also inflammation of joints, kidneys, and other organs; a rash occurs 1 to 2 weeks after exposure to a drug or foreign antigen.

In 1990 the American College of Rheumatology (ACR) performed a study designed to identify features that distinguish one form of vasculitis from others.[7] The resulting ACR classification criteria for hypersensitivity vasculitis are shown in Table 91-3.[8] The key historical element in evaluating a patient with possible hypersensitivity vasculitis is identifying exposures that may have triggered the reaction. However, in approximately half of all patients with presumed hypersensitivity vasculitis, no inciting agent can be identified. (According to the second Chapel Hill Consensus Conference nomenclature, most patients with such a presentation would be diagnosed most precisely as having cutaneous leukocytoclastic angiitis).

A long list of medications, infections, and other exposures can lead to the syndrome of hypersensitivity vasculitis. The typical history for a drug-induced hypersensitivity vasculitis is the occurrence of clinical symptoms approximately 7 to 14 days after starting a new medication. Although

From Mills JA, Michel BA, Bloch DA, et al: The American College of Rheumatology 1990 criteria for the classification of Henoch-Schönlein purpura. *Arthritis Rheum* 33:1114–1121, 1990.

virtually any medication can be associated with the induction of a hypersensitivity vasculitis, antibiotics (particularly penicillins and cephalosporins) are the most common offenders. Other common culprits are diuretics and antihypertensive agents, but when confronted with a patient who has a potential drug-induced vasculitis, it is critical to examine and potentially discontinue any medication added within a recent time frame. Drug-induced hypersensitivity vasculitides begin to resolve within days of removal of the offending agent.

Thorough efforts are also required to exclude disease in organs other than the skin, because this finding would implicate another form of vasculitis (see Figure 91-5). For example, although hypersensitivity vasculitis can mimic the skin features of microscopic polyangiitis, it does not involve the kidneys, lungs, peripheral nerves, or other internal organs and is not associated with ANCA.

Removal of the inciting agent is the most critical therapy for hypersensitivity vasculitis when the likely agent can be identified. In patients who have been exposed to multiple medications, determining the inciting agent may be difficult and may require the withdrawal of multiple agents simultaneously until the syndrome clears, typically in 1 to 2 weeks.

The prognosis for patients with hypersensitivity vasculitis depends on the inciting cause. Treatment with glucocorticoids is reserved for patients with extensive disease and can usually be discontinued within several weeks. Patients who experience repeated disease flares may need low-dose glucocorticoids to prevent recurrences.

## IgA Vasculitis (Henoch-Schönlein Purpura)

HSP is an IC-mediated form of small-vessel vasculitis that is strongly associated with IgA deposition within blood vessel walls. Many cases of HSP occur after upper respiratory tract infections. Multiple bacterial, viral, and other infectious agents have been suggested as the cause of HSP, but the true cause remains unknown. The 1990 ACR criteria for the classification of HSP are shown in Table 91-4.[9]

A major risk factor for HSP (as well as for IgA nephropathy, which has renal findings identical to those of HSP) is aberrant glycosylation of *O*-linked glycans in the hinge region of a fraction of IgA1 molecules.[10] Rather than terminating with galactose, the aberrant galactose-deficient *O*-glycans end with *N*-acetylgalactosamine (GalNAc) or sialylated GalNAc. The terminal GalNAc moiety on the aberrantly glycosylated IgA1 may in turn be recognized by antiglycan antibodies, leading to the formation of circulating ICs that are deposited in the skin, joints, kidneys, and other organs. However, a high serum galactose-deficient–IgA1 level is not sufficient for the development of clinical symptoms. A "second hit" in the form of another environmental or inherited risk factor is required to produce HSP, which probably explains why multiple types of infections and many different drugs (e.g., antibiotics) have been linked etiologically with HSP.

The hallmarks of HSP include an upper respiratory tract infection, followed by a syndrome characterized by a purpuric rash, arthralgias, abdominal pain, and renal disease. HSP is usually viewed as a disease of childhood, and the majority of cases affect children younger than 5 years. However, adults can also be affected by HSP and have a greater tendency toward a prolonged disease course (with recurrent bouts of purpura) than do children.[11] Colicky abdominal pain, presumably secondary to gastrointestinal vasculitis, is a common characteristic of HSP and frequently occurs within a week after the onset of rash. Sometimes the gastrointestinal symptoms of HSP precede the onset of purpura, leading to a diagnostic quandary and occasionally to exploratory surgery. Endoscopy can demonstrate purpura in the upper or lower intestinal tract. Mild glomerulonephritis is common and generally self-limited, although end-stage renal disease develops in some patients.

In children with mild manifestations, the clinical history alone may be sufficient to confirm the diagnosis. In more serious cases (e.g., in the presence of renal involvement) or when there is sufficient doubt about the diagnosis, biopsy of an involved organ is essential. Unlike in other forms of IC-mediated disease, however, DIF reveals florid IgA deposition. In the proper clinical setting, this finding is diagnostic of HSP. Other forms of small-vessel vasculitis may have small quantities of IgA within blood vessels, but IgA is not the predominant immunoreactant in such cases.

In mild cases of HSP, no specific therapy is necessary. Even for patients with glomerulonephritis, it is difficult to show that treatment with glucocorticoids or immunosuppressive agents significantly alters the outcome. Nonetheless, it is often prudent to treat aggressive renal involvement with an immunosuppressive regimen including high-dose glucocorticoids. Mycophenolate mofetil is an option in patients with severe renal disease for both additional immunosuppression and steroid-sparing effects.

Recurrent skin disease, often consisting of multiple episodes occurring over many months, is common. However,

even in patients with recurrent disease, the rule is for the disorder to subside and to resolve completely over a few months to a year. In a minority of patients, some evidence of permanent renal damage persists in the form of proteinuria and hematuria. Renal failure develops as a result of HSP in fewer than 5% of patients.

## Cryoglobulinemic Vasculitis

Cryoglobulins are immunoglobulins characterized by a tendency to precipitate from serum under conditions of cold.[12] These proteins, detectable to a varying degree in a wide array of inflammatory conditions, do not always cause disease. In some patients, however, cryoglobulins bind to circulating antigen (e.g., portions of the hepatitis C virion), are deposited in the walls of small- and medium-sized blood vessels, and activate complement, leading to cryoglobulinemic vasculitis.

In contrast to most other forms of IC-mediated vasculitis, cryoglobulinemia tends to involve small- and medium-sized blood vessels. Thus the syndrome of cryoglobulinemic vasculitis can be associated with the development of large cutaneous ulcers, digital ischemia, and livedo racemosa—findings characteristic of disturbances in medium-sized vessels. The first Chapel Hill Consensus Conference provided a consensus definition for mixed cryoglobulinemia (Table 91-5).[1]

Three major types of cryoglobulinemia are recognized and are defined by the specific types of immunoglobulins with which they are associated (Table 91-6). Type I, characterized by a monoclonal gammopathy (generally IgG or IgM), differs substantially from types II and III in its clinical presentation and disease associations. Type I cryoglobulinemia, associated with Waldenström's macroglobulinemia or, less frequently, multiple myeloma, is more likely to cause syndromes related to hyperviscosity (dizziness, confusion, headache, and stroke) than necrotizing vasculitis. In contrast to the monoclonal nature of type I cryoglobulinemia, types II and III are known as *mixed cryoglobulinemias* because they are composed of both IgG and IgM. In type II cryoglobulinemia, more than 90% of cases are caused by hepatitis C infection, and the cryoproteins consist of monoclonal IgM and polyclonal IgG. Cases of type II cryoglobulinemia not associated with hepatitis C are sometimes termed *essential mixed cryoglobulinemia* because their cause is not known. Type III cryoglobulinemia, typically associated with polyclonal IgG and polyclonal IgM, is associated with many forms of chronic inflammation, including infection and autoimmune disease.

Type II and III cryoglobulinemias often present with a triad of signs and symptoms: purpura, arthralgias, and myalgias. The purpura may be extensive and confluent (Figure 91-6), sometimes involving the trunk, upper extremities, and even the face; in most cases, however, the rash is confined to the lower extremities. Other organ systems commonly involved in mixed cryoglobulinemia are the kidneys and peripheral nerves. Mixed cryoglobulinemia may cause membranoproliferative glomerulonephritis that resembles lupus nephritis histopathologically. It may also cause a vasculitic neuropathy, usually with sensory symptoms

**TABLE 91-5** Chapel Hill Consensus Conference Definitions of Immune Complex–Mediated Forms of Vasculitis

| Disease | Definition |
|---|---|
| Cutaneous leukocytoclastic angiitis | Isolated cutaneous leukocytoclastic angiitis without systemic vasculitis or glomerulonephritis |
| Immunoglobulin A vasculitis (Henoch-Schönlein purpura) | Vasculitis with immunoglobulin A–dominant immune deposits, affecting small blood vessels (capillaries, venules, and arterioles); typically involves skin, gut, and glomeruli and is associated with arthralgias or arthritis |
| Essential cryoglobulinemia | Vasculitis with cryoglobulin immune deposits, affecting small blood vessels (capillaries, venules, and arterioles) and associated with cryoglobulins in serum; skin and glomeruli are often involved |

**Figure 91-6** Confluent purpura in mixed cryoglobulinemia. Extensive purpuric lesions are often so numerous that they form confluent areas of cutaneous involvement.

**TABLE 91-6** Types of Cryoglobulins

| Cryoglobulin | RF Positivity | Monoclonality | Associated Diseases |
|---|---|---|---|
| Type I | No | Yes (IgG or IgM) | Hematopoietic malignancy (multiple myeloma, Waldenström's macroglobulinemia) |
| Type II | Yes | Yes (polyclonal IgG, monoclonal IgM) | Hepatitis C; other infection; Sjögren's syndrome; SLE |
| Type III | Yes | No (polyclonal IgG and IgM) | Hepatitis C; other infection; Sjögren's syndrome; SLE |

Ig, Immunoglobulin; RF, rheumatoid factor; SLE, systemic lupus erythematosus.

predominating over motor symptoms. Finally, in rare cases, cryoglobulinemia is associated with alveolar hemorrhage.

Skin biopsy is the most straightforward method of confirming the diagnosis. Light microscopy of purpuric lesions demonstrates leukocytoclastic vasculitis. In addition, DIF studies reveal various types of immunoglobulin and complement deposition, depending on the type. In type II cryoglobulinemia, for example, DIF reveals IgG and IgM deposition, as well as complement components. Serologic testing may also yield clues to the presence of mixed cryoglobulinemia. To assay serum cryoglobulins, the blood is collected in a prewarmed apparatus, allowed to clot at 37° C before processing, and then refrigerated at 4° C for several days. The percentage of the serum occupied by the cryoprecipitate is referred to as the "cryocrit." The difficulties involved in performing cryoglobulin assays often lead to false-negative results. Nonspecific serologic testing may also implicate mixed cryoglobulinemia. As noted, detection of cryoglobulins is not always associated with disease.

A strong clue is the presence of an extremely low level of C4, reduced out of proportion to C3. In addition, the monoclonal component of type II cryoglobulins almost invariably has rheumatoid factor activity (i.e., it binds to the Fc portion of IgG). Thus essentially all patients with type II cryoglobulinemia have high titers of rheumatoid factor. C4 levels, rheumatoid factor titers, and cryocrits all fare poorly as markers of clinical disease activity, often remaining abnormal in the face of clinically improved disease.

In recent years, substantial progress has been made in the treatment of cryoglobulinemia. Until recently, antiviral therapies with the combination of interferon-α and ribavirin were believed to be the optimal treatment for mixed cryoglobulinemia associated with hepatitis C infection. The impact of more recent curative therapies for hepatitis C, such as sofosbuvir, on management of hepatitis-associated cryoglobulinemia still needs to be determined. Dual strategies that combine anti-viral therapies and B cell depletion approaches with rituximab might be synergistic and lead to long-term treatment responses.[13] The rationale behind rituximab use in persons with cryoglobulinemia is that peripheral B lymphocyte depletion will lead to a reduction in plasma cells that produce cryoglobulins. Studies of these treatment modalities have suggested that disease relapses are associated with the absence of virologic control and peripheral B cell recovery, implying the need to combine the two treatment strategies. The optimal timing of anti-viral and B cell depletion strategies is not clear. However, one reasonable approach is to initiate anti-viral strategies first and then to use rituximab within several weeks.

Patients who present with overwhelming illness, such as the unusual patient with alveolar hemorrhage or symptoms of hyperviscosity, are candidates for plasma exchange, with the goal of removing the pathogenic ICs as quickly as possible. One approach is to perform plasma exchange every other day with concomitant glucocorticoid therapy for a total of seven exchanges or until sufficient clinical improvement occurs, followed by B cell depletion after plasma exchange is complete (so the B cell depletion agent is not removed by plasma exchange).

The prognosis of patients with cryoglobulinemia generally depends on the underlying cause. The outcome of type I cryoglobulinemia relates closely to the success in treating the cause. Type II or III cryoglobulinemia secondary to hepatitis C can be treated effectively if the viral infection is responsive to therapy. If patients do not tolerate anti-viral therapy well or if the treatment is ineffective, low to moderate doses of prednisone may be required to control the disease.

Patients with mixed cryoglobulinemia whose disease is not associated with either hepatitis C or a lymphoproliferative malignancy often respond well to rituximab plus glucocorticoids, with glucocorticoids tapered over several weeks. Such patients often require regular treatment with rituximab (e.g., every 6 months) to prevent return of the disease.

## Hypocomplementemic Urticarial Vasculitis

Three different syndromes of UV are recognized: normocomplementemic UV, hypocomplementemic UV (HUV), and the HUV syndrome (HUVS). Normocomplementemic UV is typically a self-limited subset of hypersensitivity vasculitis. In chronic cases, normocomplementemic UV must be distinguished carefully from neutrophilic urticaria, a persistent form of urticaria not associated with vasculitis. In contrast, HUV is more likely to be a chronic disorder that has certain overlapping features with SLE: low serum complements, autoantibodies, and an interface dermatitis characterized by immunoreactant deposition (complement and immunoglobulins) at the dermal-epidermal junction in a pattern essentially identical to the lupus band test. Finally, HUVS is a severe form of the disease associated with extracutaneous disease and an array of organ system findings atypical of SLE.[14] For example, HUVS may be associated with uveitis, chronic obstructive pulmonary disease (COPD), and angioedema.

Unlike common urticaria, the UV lesions are frequently associated with moderate pain, burning, and tenderness in addition to pruritus. Whereas common urticaria typically resolves completely within 24 to 48 hours, UV lesions may take days to resolve completely, often leaving residual hyperpigmentation; they may worsen without therapy. Patients with HUV or HUVS may present with purpuric lesions that are more dominant than urticarial lesions.

The skin lesions in UV tend to be centripetal, favoring the trunk and proximal extremities more than dependent regions. The lesions are painful and associated with a burning sensation rather than the pruritus of common urticaria. Biopsy of an urticarial wheal in UV demonstrates evidence of leukocytoclastic vasculitis, including injury to the endothelial cells of the postcapillary venules, erythrocyte extravasation, leukocytoclasis, fibrin deposition, and a perivascular neutrophilic (or, less commonly, lymphocytic) infiltrate. DIF demonstrates IC deposition around blood vessels in the superficial dermis and a striking deposition of immunoglobulins and complement along the dermal-epidermal junction. In the proper setting, these findings (interface dermatitis and immunoreactant deposition within blood vessels) are diagnostic of HUV. HUVS, in contrast, is a clinical diagnosis based on the presence of UV and the occurrence of typical features in extracutaneous organ systems.

Some cases of HUV respond to therapies commonly used for the treatment of SLE, including low-dose prednisone, hydroxychloroquine, dapsone, or other immunomodulatory agents. Serious cases of HUVS, particularly those presenting with glomerulonephritis or other forms of serious organ involvement, may require high doses of glucocorticoids or biologic agents such as inhibitors of tumor necrosis factor. Both COPD and cardiac valve abnormalities are associated with HUVS and may require specific treatment as well.

The prognosis of UV is often linked to the disorder with which it is associated. SLE, COPD, angioedema, and valvular abnormalities are all known to occur in association with this disorder and may strongly influence both quality and quantity of life. Some cases of HUV and HUVS resolve completely after courses of immunosuppression.

## Erythema Elevatum Diutinum

EED is a rare, distinctive form of leukocytoclastic vasculitis limited to the skin.[15] The disorder is distinctive because of the unusual distribution of skin lesions (found symmetrically over the extensor surfaces of joints) and the prompt response to sulfone medications. The cutaneous findings are typical of any small-vessel vasculitis, with a predominance of papules, plaques, and nodules. Early lesions are often pink or yellowish and then become red or purple (Figure 91-7). The natural history of untreated lesions is for them to persist for years, becoming doughy or hard with time. The lesions have a predilection for the skin overlying the small joints of the hands and the knees, and they can also affect the buttocks. The trunk is generally spared.

The principal histopathologic findings of EED are leukocytoclastic vasculitis with fibrinoid necrosis. Although an IC basis is suspected in this disorder, DIF studies are not distinctive. EED has been associated with various CTDs, rheumatoid arthritis, other forms of vasculitis such as GPA, human immunodeficiency virus infections, and paraproteinemias (particularly IgA). EED typically responds promptly to dapsone or sulfapyridine, but long-term therapy may be required because skin lesions recur after cessation of treatment.

## Vasculitis Associated with Immune-Mediated Disease

Vasculitis rarely occurs in autoimmune diseases without overt manifestations of the underlying disorder. The diseases typically complicated by vasculitis include those related to SLE: lupus itself, mixed CTD, Sjögren's syndrome, and overlap syndromes. Although vasculitis clearly occurs in some settings, it is commonly overdiagnosed in attempts to explain perplexing disease features in patients with known rheumatic illnesses. For example, neuropsychiatric SLE is generally not caused by a true vasculitis but rather by other mechanisms that remain poorly defined. Whenever possible, the clinical hypothesis of vasculitis should be confirmed by biopsy.

Cutaneous vasculitis in these diseases almost invariably is associated with hypocomplementemia and high titers of anti-nuclear antibodies (ANAs). DIF examination of skin lesions shows granular IgG and C3 deposition in and around dermal vessels, with or without IgM, reflecting the contribution of ICs to disease pathogenesis. The phenomenon of the "in vivo ANA" is also observed in keratinocytes and dermal cells in DIF studies (Figure 91-8).

Vasculitis in patients with SLE-related disorders is more likely than other forms of vasculitis to be associated with a lymphocytic predominance. One variant of autoimmune disease–associated cutaneous vasculitis, the so-called benign hypergammaglobulinemia of Waldenström, is usually a true lymphocytic vasculitis. Patients with this disorder invariably have anti-Ro antibodies (also known as SS-A), and many have subclinical Sjögren's syndrome. Lymphocytic vasculitis typically demonstrates less disruption of blood vessel architecture than does leukocytoclastic vasculitis, perhaps because lymphocytes contain fewer of the

**Figure 91-7** Erythema elevatum diutinum. Nodules typically form over the extensor surfaces of the knuckles and other joints.

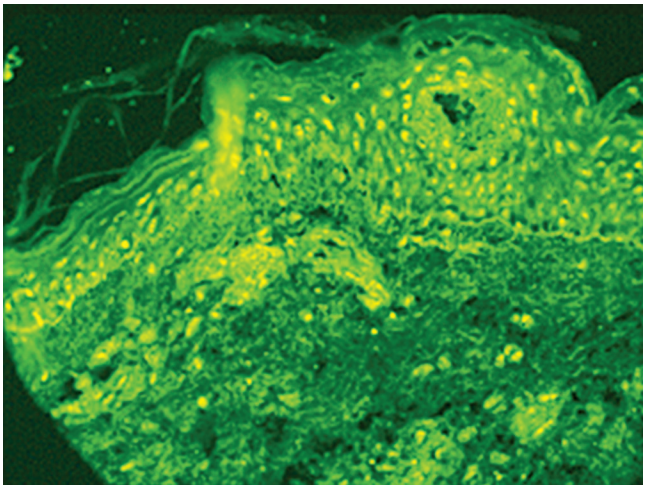

**Figure 91-8** Direct immunofluorescence study in connective tissue disease–associated vasculitis reveals tissue deposits of immunoglobulin G and an "in vivo anti-nuclear antibody" phenomenon. This phenomenon is caused by the binding of immunoreactants to targets within the nuclei of epidermal cells.

destructive enzymes found within neutrophil granules. Fibrinoid necrosis, for example, is rare in lymphocytic vasculitis. True lymphocytic vasculitis is nearly always confined to the small blood vessels of the superficial papillary dermis. Even in Sjögren's syndrome, however, the histopathology encountered in most cases is that of leukocytoclastic vasculitis.

### Rheumatoid Vasculitis

RV must be distinguished from the isolated, periungual digital vasculitis that, in the absence of severe involvement, does not require intensive, vasculitis-specific therapy. Isolated digital vasculitis in patients with rheumatoid arthritis, characterized by splinter-like lesions in the periungual region (Bywaters lesions), is not necessarily associated with a poorer prognosis than rheumatoid arthritis without digital vasculitic lesions and does not require specific therapy for vasculitis. In contrast, RV is a potentially devastating complication that may involve both medium- and small-sized blood vessels and requires the most aggressive therapeutic interventions. Many clinical manifestations of RV are indistinguishable from polyarteritis nodosa, although microaneurysms are less common in RV. RV classically occurs in patients with nodular, rheumatoid factor–positive, destructive disease who have few clinical indications of active synovitis at the time vasculitis begins. However, RV occasionally complicates early disease.

The most common presentation of RV includes purpuric lesions with or without evidence of concomitant medium-vessel vasculitis. DIF examination of the skin lesions shows granular IgM and C3 deposition in vessels, consistent with an IC-mediated pathophysiology in which rheumatoid factor, complement, and cryoglobulins may all participate. Deep cutaneous ulcers near the malleoli are a hallmark of RV and require scrupulous local care, as well as judicious immunosuppression. Mononeuritis multiplex often complicates RV. High-dose glucocorticoids plus rituximab is an appropriate first-choice regimen for many patients with RV, with the addition of cyclophosphamide if evidence of advancing disease exists. TNF inhibitors might also be reasonable options for patients with milder disease.

## CONCLUSION

IC-mediated forms of vasculitis comprise a diverse array of inflammatory disease, with a predilection for small to medium vessels (small > medium). The clinical effects often stem directly from the biochemical features of the ICs formed in response to different stimuli. The organ specificity, treatment options, and prognosis vary widely according to the specific type of vasculitis. Some forms of IC-mediated vasculitis are self-limited or require no further intervention than removal of the inciting antigen (e.g., the medication trigger in the case of drug-induced vasculitis). Glucocorticoids are the first line of treatment for the many cases in which immunosupression is required. The role of treatment with many biologic agents remains unclear, although B cell depletion fulfills an important treatment function in may patients with mixed cryoglobulinemia, rheumatoid arthritis, and other conditions.

CHAPTER 92

# Primary Angiitis of the Central Nervous System

Rula A. Hajj-Ali • Carol A. Langford

**KEY POINTS**

- Primary angiitis of the central nervous system (PACNS) is defined as vasculitis that is confined only to the brain, meninges, or spinal cord.
- PACNS consists of subsets including granulomatous angiitis of the central nervous system (GACNS) and atypical PACNS that are differentiated by unique histologic and imaging characteristics.
- The diagnosis of PACNS is based on compatible clinical features together with evidence from spinal fluid, brain and vascular imaging, and often a brain biopsy.
- Ruling out mimics that have a similar clinical or angiographic appearance is central to the diagnosis of PACNS.
- Reversible cerebral vasoconstriction syndrome is among the most important mimics of PACNS, with treatment and outcome implications.
- The initial treatment of PACNS includes glucocorticoids either alone or in combination with cyclophosphamide based on the subset and severity of neurologic disease.
- The outcome of PACNS is variable, with the highest rate of disability and mortality seen in people with GACNS.

Vasculitis affecting the central nervous system (CNS) most commonly occurs as a manifestation of a primary systemic vasculitis or as a secondary vasculitis in settings such as connective tissue diseases or infections. When the disease is confined only to the CNS (the brain, meninges, and spinal cord), it is referred to as *primary angiitis of the central nervous system* (PACNS).

PACNS is a rare disease that was first reported as a distinct clinical pathologic entity by Cravioto and Feigin in 1959.[1] The disease initially was described as fatal "noninfectious granulomatous angiitis with a predilection for the nervous system." Other reports of similar clinicopathologic phenotypes emerged in the literature, and "granulomatous angiitis of the central nervous system" was proposed to describe this entity.[2,3] Different terms subsequently surfaced in the literature, such as *isolated angiitis of the CNS* to encompass cases that were characterized by nongranulomatous pathologic findings.[4] Currently, PACNS is a well-accepted term for this disease that emphasizes the sole involvement of the CNS.[5,6] After the description of diagnostic criteria for PACNS proposed by Calabrese and Mallek in 1988[5] and the potential for effective treatment,[7] published cases in the literature increased tremendously, and more than 500 cases have now been described worldwide.[8,9]

## EPIDEMIOLOGY

Because of its rarity and our evolving understanding of this disease, the true incidence of PACNS is difficult to calculate.[9] In the recent era, the estimated annual incidence rate of PACNS is 2.4 cases per 1 million person-years.[9] Middle-aged men are often affected by PACNS, with a median age at onset of approximately 50 years and a male-to-female ratio of approximately 2:1.[5,6,9]

## GENETICS

The pathogenesis of PACNS is not well understood. To date, no evidence has been found to suggest a genetic predisposition, although this possibility remains under active investigation.

## CLINICAL FEATURES

**KEY POINTS**

- PACNS is divided into subsets that include granulomatous angiitis of the central nervous system (GACNS) and atypical PACNS.
- Mass-like lesions can occur in people with PACNS.
- Clinical features of GACNS typically include chronic insidious headaches along with diffuse and focal neurologic deficits.

Great progress has been made toward understanding the clinical features of PACNS despite the many challenges, which include the lack of highly specific diagnostic modalities, the sparse material for research, and the lack of controlled clinical trials. In the recent era, specific clinical and pathologic subsets of PACNS have been identified that have prognostic implications.[10-13]

### Proposed Criteria for Primary Angiitis of the Central Nervous System

In 1988, Calabrese and Mallek[5] proposed diagnostic criteria for PACNS that emphasized the importance of ruling out mimics when diagnosing PACNS. These criteria include (1) the presence of an unexplained neurologic deficit after

thorough clinical and laboratory evaluation; (2) documentation by cerebral angiography and/or tissue examination of an arteritic process within the CNS; and (3) no evidence of a systemic vasculitides or any other condition to which the angiographic or pathologic features could be secondary.

In 2009, Birnbaum and Hellmann[12] proposed changes to the criteria described by Calabrese and colleagues, incorporating levels of diagnostic certainty in their assessment. They proposed use of the term *definite diagnosis of PACNS* when tissue biopsy findings provide confirmation of vasculitis and a *probable diagnosis of PACNS* when the diagnosis is based on high-probability findings on an angiogram in the absence of tissue confirmation but with consideration of cerebrospinal fluid (CSF) profiles and neurologic symptoms to discriminate between PACNS and its mimics.

Although the original criteria by Calabrese and Mallek served as a platform of literature-based research, their interpretation has changed fundamentally as advancement of our diagnostic modalities has revealed many unexplained neurologic diseases. The importance of ruling out mimics of PACNS remains essential in the diagnostic approach of patients with suspected PACNS.

## CLINICAL SUBSETS

The original pathologic reports of PACNS as a granulomatous angiitis imposed a histologic-based nomenclature on the disease that led to the original name *granulomatous angiitis of the CNS* (GACNS). Until the 1980s, PACNS was largely considered a homogeneous entity with a uniform clinical picture and a grave prognosis. This paradigm was challenged with the introduction of direct vascular imaging as a diagnostic tool and the recognition that nongranulomatous pathologic findings occur in PACNS.

Initial attempts at subclassification of PACNS described three broad subsets: GACNS, benign angiopathy of the CNS (BACNS), and "atypical" PACNS.[14] It has since become recognized that BACNS is part of the reversible cerebral vasoconstriction syndrome (RCVS),[11] with the other PACNS subsets now being defined by pathologic or radiographic features.

### Granulomatous Angiitis of the Central Nervous System

GACNS is a subset of PACNS that is described as a clinicopathologic entity characterized by granulomatous angiitis confined to the brain. GACNS is a rare subset of PACNS, in which patients clinically present with chronic insidious headaches along with diffuse and focal neurologic deficits. Because the disease is confined to the brain, meninges, or spinal cord, signs and symptoms of systemic inflammatory diseases are usually lacking. The diagnosis of this subset is confirmed by the pathologic findings of granulomatous angiitis (Figure 92-1). Typically the CSF findings include those of an aseptic meningitis picture with negative staining for microorganisms. GACNS predominantly affects middle-aged men. The most common findings on neuroimaging include infarcts, most often bilateral, as well as high-intensity T2-weighted fluid attenuation inversion recovery (FLAIR) lesions on magnetic resonance imaging (MRI) in the subcortical white matter and deep gray matter. A cerebral angiogram is not the diagnostic modality of choice given its poor spatial resolution in the detection of small vessel vasculitis, which mainly occurs in GACNS.

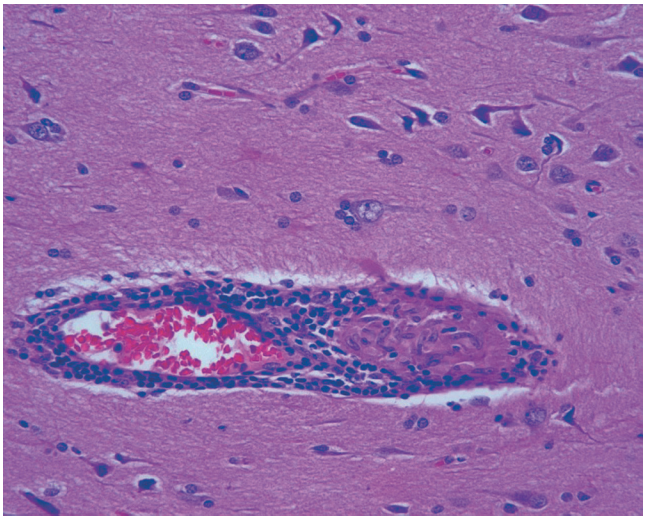

**Figure 92-1** Histopathologic findings of patients with granulomatous angiitis of the central nervous system vasculitis.

### Atypical Central Nervous System Vasculitis

Atypical CNS vasculitis, a subset of PACNS, comprises multiple manifestations of PACNS that are clinically, radiologically, or pathologically distinct from GACNS. Atypical PACNS is the most frequent and heterogeneous subset of PACNS. Included in this subset are patients with specific presentations such as lesions or patients with pathologic findings of lymphocytic infiltration rather than granulomatous angiitis.

#### Mass-like Presentation

Mass-like (ML) presentation is a rare manifestation of PACNS that occurs in less than 5% of cases. This presentation has gained attention after the recent report of a series of 38 patients with histologically confirmed PACNS who presented with a solitary cerebral mass.[15] Typically the diagnosis is unanticipated and is confirmed after pathologic examination with either biopsy samples or surgical excision of the mass. Unfortunately, no specific features on clinical assessment, neuroimaging, cerebral angiography, or CSF examination can reliably distinguish ML-PACNS from other more common causes of a solitary cerebral mass. Use of appropriate stains and cultures to rule out mycobacterial, fungal, or other infections and immunohistochemistry/gene rearrangement studies to exclude lymphoproliferative disease are essential to secure the diagnosis and exclude concomitant infectious or malignant processes.

#### Cerebral Amyloid Angiitis

Amyloid protein, in particular amyloid-β peptide, a fragment of the amyloid precursor peptide, can deposit in the brain, causing disease ranging from Alzheimer's disease to

cerebral amyloid angiopathy (CAA). CAA-related inflammation and angiocentric inflammatory reaction in CAA is referred to as amyloid-β–related angiitis (ABRA).[16] Patients with ABRA tend to be older and more prone to hallucinations and mental status changes than are other patients with PACNS. MRI cannot distinguish between ABRA and other forms of PACNS, although ABRA has a higher incidence of cerebral hemorrhage. ABRA carries a poor outcome, which could be related to older age and comorbidities.

### Angiographically Defined Central Nervous System Vasculitis

The poor specificity of the cerebral angiogram poses a major challenge in the diagnosis of PACNS. When the diagnosis of PACNS is based on angiographic findings, a thorough evaluation should be performed to rule out mimics, especially RCVS.[17,18]

### Spinal Cord Presentation

Spinal cord presentation of PACNS is a rare subset in which disease is present only in the spinal cord. The diagnosis is usually made by biopsy.[19]

### Nongranulomatous PACNS

Pathologic findings of lymphocytic infiltration rather than granulomatous findings can occur in PACNS. In this category, ruling out secondary causes of CNS vasculitis, such as infectious or lymphoproliferative diseases, should be emphasized. Adequate staining and immunophenotyping should always be carefully carried out in this category.

## DIAGNOSIS AND DIAGNOSTIC TESTS

**KEY POINTS**

- **Spinal fluid, brain and vascular imaging, and brain biopsy are central to the diagnosis of PACNS and the process of ruling out other diseases.**
- **Abnormal spinal fluid is found in 80% to 90% of patients with PACNS.**
- **Abnormalities on a cerebral angiogram are not specific for PACNS and can be seen in a wide range of other settings.**
- **Reversible cerebral vasoconstriction syndrome is an important mimic of PACNS that is characterized by thunderclap headaches, normal CSF, and abnormal findings of a cerebral angiogram in which the changes resolve within 12 weeks.**
- **Other important entities in the differential diagnosis of PACNS include infection, lymphoproliferative disease, primary systemic vasculitis, connective tissue disease, and thromboembolic disease.**

The diagnosis of PACNS is challenging because of the nonspecific clinical presentation, the lack of highly specific laboratory and radiologic tests, and the difficulty of obtaining pathologic material.

### Diagnostic Tests

#### Laboratory Findings

Elevation of acute-phase reactants, anemia, and thrombocytosis are not typical of PACNS, and if present, they should raise the possibility of a primary systemic vasculitis or another underlying disease. Laboratory testing to rule out connective tissue diseases and thromboembolic abnormalities should be performed. Infectious workup with appropriate cultures, serologies, and polymerase chain reaction testing should be directed by clinical and diagnostic findings and host risk factors.

#### Cerebrospinal Fluid Analysis

CSF is an important tool in the evaluation of PACNS. Although CSF findings are nonspecific in PACNS, their value lies in ruling out other entities. Obtaining appropriate CSF cultures, microbiologic stains, cytology, and flow cytometry is crucial in ruling out infectious and neoplastic disease. Elevated protein levels, modest lymphocytic pleocytosis, and occasionally oligoclonal bands and elevated IgG synthesis characterize the CSF in 80% to 90% of patients with pathologically documented PACNS.[5,20,21] The median CSF white blood cell count is approximately 20 cells/μL, and the median CSF protein level is approximately 120 mg/dL.[5,9]

#### Radiologic Evaluation

MRI is a sensitive modality for the diagnosis of PACNS, reaching 90% to 100%.[9,22] Abnormalities include infarcts in 50% of patients, commonly affecting the cortex and the subcortex bilaterally.[9,23] Affected areas include subcortical white matter, followed by deep gray matter, deep white matter, and the cerebral cortex.[24] Hyperintense lesions on T2-weighted sequences are common but not specific for PACNS.[25] Other abnormalities include mass lesions in 5% of patients,[15] leptomeningeal enhancement in 8% of cases,[9] and gadolinium-enhanced intracranial lesions in about one-third of patients.[9]

Cerebral vasculature imaging by catheter-directed dye angiogram or through magnetic resonance angiography (MRA) is an important modality in the diagnosis of PACNS. Alternating areas of dilatation and stenosis characterize the angiographic findings in PACNS and typically involve the vasculature on both sides but sometimes can involve single vessels.[26] Other angiographic features include smooth tapering of one or multiple vessels. Although cerebral angiograms may visualize abnormalities in medium-sized vessels, they have limited sensitivity to detect abnormalities in small vessels that are less than 500 μm in diameter. Although cerebral angiography is valuable, its specificity for the diagnosis of PACNS can be as low as 25%.[27] The reported "typical" angiographic findings for vasculitis are not specific to PACNS and can be encountered in atherosclerosis, radiation vasculopathy, or vascular spasm.[26,27] Moreover, a cerebral angiogram carries a poor positive predictive value in the diagnosis of PACNS in that the angiographic findings seen in RCVS can be consistent with those found in PACNS.[28] Vascular studies thus should be interpreted with caution and should not be considered the diagnostic

"gold standard" in PACNS. Ongoing research using high-resolution contrast-enhanced MRI to look at the vessel wall characteristics of wall thickening and wall enhancement is under way.[29] This promising technique may enable us to characterize and differentiate between CNS vasculitis, RVCS, and intracranial atherosclerosis. Recent reports indicate that vessel wall enhancement occurs at a much higher rate in PACNS compared with RCVS. Larger studies are needed to validate these interesting findings.

### Brain Biopsy

Brain biopsy is thought to carry a low morbidity and mortality in patients with PACNS[14] and is an important part of the evaluation to confirm the diagnosis and rule out mimics. When a brain biopsy is performed, an alternative diagnosis is identified in 30% to 40% of cases.[30] The interpretation of the brain biopsy results should take into consideration the potential for false-negative results because of the patchy degree of involvement and the small amount of tissue that often is able to be obtained. The finding of vasculitis on pathologic examination does not exclude the diagnosis of infection or malignancy, and appropriate stains and markers should be pursued for accurate diagnosis.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis algorithm of PACNS is large because of the lack of highly specific clinical features or laboratory or imaging findings (Table 92-1). Excluding other entities that can have similar findings is critical in confirming a diagnosis of PACNS. Certain disease categories in particular should be considered and warrant further detailed discussion.

### Reversible Cerebral Vasoconstriction Syndromes

Distinguishing RCVS, the leading mimic of PACNS, is important because it has different implications for treatment and outcome (Table 92-2). RCVS consists of a group of disorders characterized by acute-onset headaches and reversible cerebrovasoconstriction.[11] These disorders include Call-Fleming syndrome, drug-induced angiopathy, migraine angiitis, BACNS, postpartum angiopathy, and drug-induced vasospasm. The clinical features of RCVS include acute onset of severe headaches, with or without neurologic deficit, with evidence of cerebral vasoconstriction that is reversible. The headaches are usually recurrent thunderclap headaches and can be precipitated by straining and coughing. RCVS can be associated with strokes (39%), generalized tonic-clonic seizures (17%), convexity subarachnoid hemorrhage (34%), lobar hemorrhage (20%), and brain edema (38%).[18] RCVS occurs more frequently in women than men. In contrast to PACNS, findings of CSF analysis are generally normal in people with RCVS except when a concomitant disorder or subarachnoid bleeding is present. The diagnosis of RCVS is usually considered when cerebral vascular imaging reveals multiple areas of smooth or tapered arterial narrowing followed by segments of normal-caliber or distended arteries. Typically, arterial narrowing involves multiple intracerebral arteries and their branches in both

**TABLE 92-2** Differentiating Clinical and Radiologic Features between Reversible Cerebral Vasoconstrictive Syndrome and Primary Angiitis of the Central Nervous System

| Feature | RCVS | PACNS |
|---|---|---|
| Gender | Female predominant | Male predominant |
| Cerebrospinal fluid | Normal | Abnormal |
| Normal magnetic resonance image | 10%-15% | Very rare |
| Abnormal angiogram | 100% | 40%-50% |
| Headache pattern | Recurrent thunderclap | Insidious, chronic |
| Infarct pattern | Watershed | Small, scattered |
| Lobar hemorrhage | Common | Extremely rare |
| Convexity subarachnoid hemorrhage | Common | Very rare |

PACNS, Primary angiitis of the central nervous system; RCVS, reversible cerebral vasoconstrictive syndrome.

hemispheres, resulting in severe arterial narrowing. The diagnosis of RCVS is secured when repeat vascular imaging reveals reversibility of the cerebral vascular abnormalities, often occurring in about 6 to 12 weeks, which is in contrast to the fixed angiographic abnormalities encountered in PACNS. Controlled trials to direct treatment of RCVS are lacking. Calcium channel blockers are used for symptomatic treatment of the headaches, although no evidence exists that they alter the clinical outcome. Some experts prescribe glucocorticoid therapy, although no evidence exists that it improves the outcome.

## Primary Systemic Vasculitides

Primary systemic vasculitides such as granulomatosis with polyangiitis (GPA), microscopic polyangiitis, eosinophilic granulomatosis with polyangiitis (EGPA; Churg-Strauss syndrome), polyarteritis nodosa, or Behçet's disease can affect the CNS, leading to inflammation and vasculitis. In GPA, CNS disease occurs in 7% to 11% of patients and presents in three ways: direct invasion of granuloma from extracranial sites, remote intracranial granuloma, and, rarely, as a result of CNS vasculitis.[31] The diagnosis of CNS vasculitis is often made on the basis of radiologic findings and by exclusion of other causes of the neurologic deficits, especially infection.[32] As in GPA, the diagnosis of CNS vasculitis in EGPA is often presumed without histologic confirmation when other mimics are excluded. Neuro-ophthalmologic manifestations including amaurosis fugax, superior oblique palsy, ischemic optic neuropathy, fourth cranial palsy, and scattered areas of retinal infarction are common presentations of CNS vasculitis in people with EGPA.[33,34] In Behçet's disease, CNS involvement occurs in 14% of cases, manifesting as meningoencephalitis involving the brain stem and rarely as a consequence of thrombosis and inflammation of the dural venous sinuses.[35-37] Pathologic evaluation in neuro-Behçet's disease typically shows a mononuclear infiltration around the small vessels of the brain, including the venous system, which is not a typical finding in PACNS.[38] True CNS vasculitis rarely occurs in Behçet's disease.[39]

## Systemic Autoimmune Diseases

The brain is a common target in connective tissue diseases. In systemic lupus erythematosus (SLE), CNS involvement occurs in 14% to 80% of adults and in 22% to 95% of children.[40] Multifocal microinfarcts, cortical atrophy, gross infarcts, hemorrhage, ischemic demyelination, and patchy multiple-sclerosis–like demyelination are typical findings in neuropsychiatric lupus. The most common microscopic brain finding in SLE is microvasculopathy, described as "healed vasculitis" consistent with hyalinization, thickening, and thrombus formation.[41,42] Rheumatoid arthritis, Sjögren's syndrome, and mixed connective tissue disease rarely affect the CNS in a vasculitic pattern.[43] CNS vasculitis is typically a late occurrence in these diseases.

## Infections

Infections are one of the most important entities that should be ruled out when considering PACNS. Vasculitis can occur in the setting of HIV, often presenting as multifocal cerebral ischemia with pathologic findings of angiocentric lymphoproliferative lesions.[44] In addition, HIV can result in granulomatous arteritis[45] or can affect the brain as a result of co-infections such as syphilis. *Treponema pallidum* infection can affect vessels in the subarachnoid space and result in thrombosis, ischemia, and infarction that can mimic PACNS.[46] Other infectious agents that have predilection to the brain include varicella-zoster virus (VZV). VZV affects the brain either by involvement of large cerebral vessels, often affecting the proximal segments of the anterior and middle cerebral arteries in immunocompetent people, or small vessel disease in immunocompromised patients.[47] A history of VZV rash is usually although not always elicited before the CNS involvement. The diagnosis of VZV angiitis is confirmed by finding VZV DNA in CSF or by the presence of reduced serum/CSF ratios of VZV IgG.[48] Tuberculosis affecting the CNS is an important cause of CNS vasculitis in endemic areas, and care must be taken to exclude it. Hepatitis C,[49] West Nile virus,[50] parvovirus B19,[51] and rarely herpes simplex virus[52] can cause CNS vasculitis. Cytomegalovirus can cause CNS vasculitis as an opportunistic infection in immunocompromised people.[53] Rarely, cysticercosis can involve middle-sized cerebral arteries.[54] A travel history and history of exposures are important features of the workup of patients with suspected PACNS.

## Lymphoproliferative Diseases

Lymphoproliferative disease with predilection to the vascular wall, such as lymphomatoid granulomatosis (LG), can cause CNS vasculitis, leading to multiple small cortical infarcts and pathologic findings of multifocal angiocentric, angiodestructive lymphoma.[55] Concomitant HIV infection is common with LG and should be ruled out.[56] Rarely, LG is associated with other systemic autoimmune diseases such as Sjögren's syndrome.[57] Other lymphoproliferative diseases such as CNS lymphoma and intravascular lymphoma can mimic PACNS.

### Miscellaneous

Atherosclerotic involvement of the intracerebral arteries is common and is often a consideration in the workup of PACNS. The poor specificity of the cerebral angiogram poses a major limitation in differentiating inflammatory causes from other vasculopathies. However, the lack of inflammatory changes of the CSF and the presence of multiple atherosclerotic risk factors should raise suspicion for atherosclerotic disease. Other entities such as antiphospholipid antibody syndrome, hypercoagulable states, and thromboembolic causes should be carefully ruled out. The workup of PACNS should include a transesophageal echocardiogram and a hypercoagulable profile to rule out thromboembolic causes, especially in patients presenting with recurrent strokes. Other rare diseases that mimic the angiographic findings of PACNS include Moyamoya disease, small vessel arterial dissection, cerebral autosomal-dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), radiation vasculopathy, and thromboangiitis obliterans.[58]

## TREATMENT

**KEY POINTS**

- No standardized trials relating to the treatment of PACNS have been conducted.
- Typically, GACNS is initially treated with glucocorticoids and cyclophosphamide.
- The treatment of PACNS subsets besides GACNS is based on the diagnostic subset and severity of neurologic impairment.

The treatment of PACNS is guided by expert opinion and reports of case series, as well as by extrapolation from controlled trials relating to primary systemic vasculitis. To date, no controlled trials have been conducted to investigate the treatment of PACNS. Thus it is not possible to determine a specific treatment algorithm, and therapy is based on the subtype and neurologic severity.

The report of successful treatment of GACNS with a combination of cyclophosphamide and glucocorticoids led to the regular use of this regimen.[7] Generally, patients are treated with a combination of cyclophosphamide and high-dose glucocorticoids for 3 to 6 months until remission is achieved. Cyclophosphamide is then stopped and use of a maintenance agent is initiated, following the same principles used in small-vessel vasculitis.[59] Maintenance therapy usually consists of either azathioprine or mycophenolate mofetil and rarely methotrexate given its low CNS penetration. The duration of maintenance therapy in PACNS is not well defined.

The treatment of atypical PACNS varies highly. Multiple factors affect the treatment regimen in atypical PACNS, and the treatment is usually individualized, taking into consideration the degree of the neurologic deficit and the features of the diagnosis. All atypical PACNS cases are treated with high dose of glucocorticoids initially, and the decision to add other immunosuppressive agents is based on each individual case. ABRA and ML-PACNS are two PACNS subsets in which cyclophosphamide is considered at the outset of the treatment. Use of TNF inhibitors or rituximab in patients with PACNS that is resistant to glucocorticoids and other immunosuppressive agents has thus far been confined to case reports, which provide insufficient evidence from which to draw conclusions regarding efficacy.[60-62]

Failure to respond to cyclophosphamide should prompt evaluation for an alternative diagnosis before additional treatment with an alternative immunosuppressive agent is instituted.

Assessing disease status and defining remission are crucial steps in the course of treatment of PACNS. Permanent deficits occurring after the initial event in PACNS should not erroneously be considered to be lack of remission. Disease is considered in remission when stability or improvement of the clinical and radiologic features is achieved. Serial MRI should be obtained to help in the assessment of disease activity. Adjunctive therapy for osteoporosis prevention and prophylaxis for opportunistic infections should be incorporated into the treatment plan.

## OUTCOME

**KEY POINTS**

- PACNS has an estimated mortality rate of 10% to 17%.
- Moderate to severe disability occurs in up to 20% of patients with PACNS.

Originally, PACNS was described as a fatal disease by Cravioto,[1] but an improved outlook became possible after the description of treatment with glucocorticoids and cyclophosphamide. According to recent reports, the estimated mortality rate of PACNS varies between 10% and 17%,[9,63] with one study finding that survival correlated with the initial findings of infarcts and gadolinium-enhanced lesions on MRI.[9] Salvarani and colleagues[9] and Hajj-Ali and colleagues[63] reported that 20% of patients with PACNS had moderate to severe disability as assessed by the modified Rankin disability scores and the Barthel index, respectively. Salvarani and colleagues[9] reported an improvement in disability scores over time.

## CONCLUSION

Considerable progress has been made in our understanding of PACNS. Our ability to recognize disease mimics has substantially increased our accuracy in diagnosing PACNS. The identification of RCVS in particular has clarified many of the cases that had been erroneously diagnosed as PACNS. Effective diagnosis and management of PACNS requires a multidisciplinary team to evaluate the clinical features, obtain and interpret diagnostic tests, and determine the most effective regimen that will treat the underlying disease and minimize therapeutic toxicity.

A great need exists for controlled trials to further guide treatment for patients with PACNS in their initial and maintenance phases. Prospective evaluation of long-term cohorts is necessary to better determine the rates of disability and long-term outcome of PACNS.

CHAPTER 93

# Behçet's Disease

William S. Kaufman • Elizabeth K. McNamara • Joseph L. Jorizzo

**KEY POINTS**

- **Behçet's disease is a complex multisystem disease characterized by oral and genital ulcers and other systemic features.**
- **The diagnosis is based on the International Criteria for Behçet's Disease and includes oral aphthae, genital aphthae, ocular lesions, cutaneous lesions, and a positive pathergy test.**
- **Cutaneous lesions display a neutrophilic vascular reaction on histopathologic examination.**
- **Treatment is based on the degree of systemic involvement. Treatments include topical corticosteroids, thalidomide, and systemic immunosuppressive and biologic agents.**
- **The prognosis is variable, and patients typically have periods of exacerbations and remissions.**

Behçet's disease is a chronic, complex multisystem disease characterized by oral and genital aphthae, cutaneous lesions, and ophthalmic, neurologic, or rheumatologic manifestations. The first description of Behçet's disease is believed to be from Hippocrates in the fifth century BC.[1] The first modern account was presented in 1937 by the Turkish dermatologist Hulusi Behçet, who reported on a patient with recurrent oral and genital aphthae and uveitis.[2]

## EPIDEMIOLOGY

Behçet's disease is seen worldwide, with the highest prevalence reported in Turkey (1 per 250 inhabitants) and Japan (11.9 patients per 100,000 inhabitants).[3,4] The prevalence, and often the severity, is increased in the Middle East and the Mediterranean (i.e., the "Silk Route").[3,4] The remainder of the Asian continent has a prevalence of 7 to 30 patients per 100,000 inhabitants.[5] It is relatively uncommon in northern Europe (0.27 to 1.18 patients per 100,000 inhabitants) and the United States (5.2 patients per 100,000 inhabitants).[5,6,7] Patients commonly manifest the diagnostic criteria in the third to fourth decades of life.[8] In the past, Behçet's disease was thought to predominantly affect males, but current epidemiologic data show a more equal male-to-female ratio.[9] Overall, the male-to-female ratio has decreased during the past 20 years, with more males diagnosed in Turkey, Greece, Italy, the Middle East, and the Far East, and more females diagnosed in Korea, China, the United States, and northern Europe.[10] Males tend to have a more severe clinical course, with increased disease-associated morbidity.[11]

## ETIOLOGY AND PATHOGENESIS

Although the pathogenesis of Behçet's disease remains enigmatic, numerous factors have been implicated. Genetics, immunologic phenomena, infectious agents, inflammatory mediators, and clotting factors are likely contributors.

### Genetics

The onset of Behçet's disease is thought to be sporadic, although familial clustering (families with multiple affected members) has been reported. Individuals with a first-degree relative with the disease are at an increased risk.[12] Additionally, children of individuals with Behçet's disease may have an earlier age of onset, suggesting genetic anticipation, characterized by a progressive increase in nucleotide repeats through consecutive generations.[13] Familial occurrence differs regionally throughout the world and is more common in Korea, Israel, Turkey, and Arab countries compared with Japan, China, and Europe.[5]

Studies have shown a significant association between the human leukocyte antigen (HLA)-B51 and Behçet's disease.[14,15,16] HLA-B51-positive patients are at an increased risk for Behçet's disease (odds ratio [OR], 5.9).[17] This association is more common in the Middle East, Mediterranean, and Japan, although not seen as often in Western nations. The disease prognosis also appears to be more severe in HLA-B51-positive patients.[5] The role of HLA-B51 in Behçet's remains unclear. It may be that HLA-B51 is not directly involved in causing the disease but is closely linked to disease-related genes.[18] Candidate genes have been localized to chromosome 6 and include the class I major histocompatibility complex (MHC) chain-related gene A (MICA) (specifically, the MICA6 allele); Perth block (*PERB*); new organization associated with HLA-B (NOB); and transporter associated with antigen processing genes (TAP).[18,19] Other hypotheses suggest that HLA-B51 may contribute to the onset of Behçet's disease by serving as a heterologous antigen, either through original antigen presentation or through viral or bacterial molecular mimicry.[18,20] A genome-wide association study confirmed the HLA-B51 relationship and also identified a second, independent association within the class I MHC region.[21]

Although Behçet's disease has many features in common with the spondyloarthropathies, especially those associated with inflammatory bowel disease (IBD), the disorder in IBD patients generally evolves in a pattern resembling reactive arthritis with an erosive axial arthritis. Erosive arthritis and *HLA-B27* are not associated with Behçet's disease.[22]

## Immune Mechanisms

Immunologic factors are thought to play a major role in Behçet's disease. Heat shock proteins, cytokines, alterations in neutrophil and macrophage activity, and autoimmune mechanisms have all been implicated.[18] Heat shock proteins are released in response to stress and may be involved in stimulating a T helper cell type I immune response through interaction with Toll-like receptors.[23] Although most of the T lymphocytes thought to be involved in this reaction are of the γδ type, the diversity of T lymphocytes seen in the disease suggests a response to multiple antigens, which may account for the various symptoms seen in Behçet's.[24] Cytokines such as IL-1, IL-8, IL-12, IL-17, IL-37, and TNF seem to be involved in the pathogenesis. Although elevated cytokine levels may serve as an indicator of disease severity, it should be appreciated that plasma TNF levels may rise and fall as an acute-phase reactant along with C-reactive protein and the erythrocyte sedimentation rate.[25,26] The production of these pro-inflammatory cytokines, which are responsible for the chronic inflammation observed, may be the result of activated macrophages.[18,27] In addition to macrophage activation, neutrophil chemotaxis and phagocytosis are increased in the lesions of Behçet's disease.[18,28] This increased activity of neutrophils leads to tissue injury in the form of the neutrophilic vascular reaction seen in lesions such as aphthae, pustular cutaneous lesions, and erythema nodosum-like lesions. Circulating immune complexes also play a role in precipitating the characteristic neutrophilic vascular reaction.[29]

The role of endothelial cell dysfunction in the pathogenesis of Behçet's disease has been suggested by decreased levels of prostacyclin in the serum of Behçet's disease patients. Increased nitric oxide concentrations in the serum, synovial fluid, and aqueous humor of individuals with Behçet's may play a role in endothelial activation, resulting in vascular inflammation and thrombosis.[30,31] Elevated homocysteine levels have been cited as the cause of the increase in nitric oxide concentrations, suggesting that hyperhomocysteinemia may represent an acquired risk factor for Behçet's, which is potentially reversible.[32-34] Anti-endothelial cell antibodies have been detected in sera from patients with Behçet's disease and have been linked to disease activity and vasculitis symptoms.[35-37] Specifically, immunoglobulin (Ig)-A type anti-endothelial cell antibodies from patients with Behçet's disease have been found to react against the target protein heterogeneous nuclear ribonucleoprotein-A2/B1 (HnRNP-A2/B1), which is associated with pre-mRNA processing, metabolism, and transport.[38]

## Infectious Agents

Several studies have suggested a role for various infectious agents in the pathogenesis of Behçet's disease. No organisms, however, have been consistently isolated. Antistreptococcal antibodies have been isolated in the serum of patients with Behçet's disease.[39] Higher concentrations of *Streptococcus sanguis* have also been found in the oral flora of patients with Behçet's disease and may contribute to the development of aphthae, which are often the initial manifestation.[40] Also, sera from patients with Behçet's disease cross-react with both human α-enolase and *S. sanguis* α-enolase, suggesting antigenic mimicry.[41] In addition to streptococcal antigens, other bacteria such as *Escherichia coli* and *Staphylococcus aureus* may trigger Behçet's disease via lymphocyte activiation.[42] Additionally, a lipoprotein of *Mycoplasma fermentans* has been found in patients with Behçet's. This lipoprotein (MALP-404) contains the specific peptide motif, which is capable of being presented by *HLA-B51*.[43] Studies have also indicated that a higher rate of *Helicobacter pylori* cytotoxin-associated gene-A antibodies appears in Behçet's patients. These antibodies may cause endothelial damage via cross-reaction with endothelial antigens. *H. pylori* eradication in these patients decreases disease severity.[44]

Herpes simplex virus (HSV) DNA has been isolated from the nuclei of peripheral blood lymphocytes by polymerase chain reaction (PCR) assay in patients with Behçet's disease.[22] HSV has also been detected by PCR in biopsy samples of genital and intestinal ulcers of Behçet's patients.[42] Other studies, however, have shown no difference in the detection of HSV in Behçet's patients with and without oral aphthae.[45]

In summary, although the etiology and exact pathogenesis of Behçet's disease remain elusive, it is likely a multifactorial process involving infectious or environmental factors that trigger an autoreactive inflammatory response in a genetically predisposed individual.

# CLINICAL FEATURES

## Aphthae

Oral aphthae (Figure 93-1) are often the initial feature of Behçet's disease and constitute a requisite diagnostic feature (although some believe that Behçet's occurs in the absence of oral aphthae). Oral ulcerations usually occur in crops of 3 to 10 or more lesions, but individual lesions may occur on the buccal mucosa, gingiva, lips, and tongue. Aphthae begin as painful papules which rapidly progress to shallow ulcerations with worsening pain. Often, a white to yellow pseudomembrane adheres to the surface of the ulcer. They usually heal spontaneously without scarring during 1 to 3

**Figure 93-1** Oral aphtha in Behçet's disease.

weeks.[46] Genital ulcers typically occur on the scrotum and penis in males and on the vulva or vaginal mucosa in females. These aphthae are similar in appearance to oral lesions, but they have a greater tendency to scar, resolve during 2 to 4 weeks, and may recur less frequently than oral ulcers.[46] Lesions in the oral mucosa are generally easy to distinguish from oral HSV, but with genital lesions, HSV should be excluded by viral culture or PCR before the lesions are accepted as a diagnostic criterion for Behçet's.

## Cutaneous Manifestations

Several cutaneous manifestations of Behçet's disease have been described: erythema nodosum-like lesions, pyoderma gangrenosum-like lesions, Sweet's syndrome-like lesions, cutaneous small vessel vasculitis, and pustular vasculitic lesions (Figure 93-2) including lesions induced by trauma—the so-called *pathergy* lesion.[46] Pathergy signifies the development of erythematous pustules or papules 24 to 48 hours following puncture of the skin with a 20- to 21-gauge sterile needle.[47] Specimens from all of these lesions demonstrate a neutrophilic vascular reaction on histopathologic analysis.[48] Acneiform or pseudofolliculitis lesions should be considered nonspecific, nondiagnostic cutaneous findings because of their common occurrence in acne vulgaris and folliculitis.

## Ophthalmic Manifestations

A variety of ocular manifestations have been reported in Behçet's patients, including anterior and posterior uveitis, retinal vasculitis, and hypopyon, with secondary glaucoma, cataract formation, decreased visual acuity, and synechiae formation. Ocular involvement occurs in 83% to 95% of men and 67% to 73% of women with Behçet's disease.[49] Men have a greater tendency for eye involvement, which may cause loss of vision.[50] Ophthalmic features most often occur in the first few years of the disease, and although ocular involvement is not commonly the presenting feature of Behçet's disease, it is a major source of serious morbidity.[51] Close ophthalmologic evaluation and follow-up are critical to prevent blindness in these patients.[52] If ocular disease does not present within a few years of diagnosis, it is less likely to be a major problem.[53]

**Figure 93-2** Pustular vasculitis lesions representing a neutrophilic vascular reaction.

## Arthritis

Arthritis in Behçet's disease is typically a nonerosive, inflammatory, symmetric, or asymmetric oligoarthritis, although polyarticular and monoarticular forms are also seen. The most commonly involved joints are the knees, wrists, ankles, and elbows, with associated enthesopathy.[54] Synovial fluid reveals formation of mucin clots and inflammatory findings of nonspecific synovitis.[55] The prevalence of arthritis among different populations ranges from 40% to 60%, and joint erosions are not observed.[52] Dilsen and colleagues[56] reported that 10% of patients with Behçet's disease had sacroiliitis. However, *HLA-B27*-positive patients were not excluded from their series, and occult IBD was not excluded as required by O'Duffy and Goldstein.[57] Other studies have shown no significant difference in the occurrence of sacroiliitis between patients with Behçet's disease and the normal population. *HLA-B27*-positive patients with erosive sacroiliitis should be included in the reactive arthritis or enteropathic arthritis disease spectrum, given the erosive, axial nature of the arthritis in the *HLA-B27* pattern. This contrasts with the classically nonerosive, nonaxial nature of arthritis in Behçet's disease.

## Other Systemic Manifestations

Central nervous system (CNS) involvement is found in 5% to 10% of patients with Behçet's disease.[58] The most common manifestations include brain stem or corticospinal tract syndromes (neuro-Behçet's syndrome), venous sinus thrombosis, increased intracranial pressure secondary to venous sinus thrombosis or aseptic meningitis, isolated behavioral symptoms, or isolated headache. In rare cases, ruptured aneurysms, peripheral neuropathy, optic neuritis, and vestibular involvement can occur.[59] Both parenchymal disease and venous thrombosis can have accompanying vasculitis.[58] Poor prognosis is associated with a progressive course, parenchymal or brain stem involvement, cerebellar symptoms, and cerebrospinal fluid abnormalities.[60] Cranial and peripheral nerve involvement may also occur.

Patients with Behçet's disease may have gastrointestinal lesions that resemble orogenital aphthae. These occur most commonly in the terminal ileum, cecum, colon, and esophagus.[33] Large aphthae may lead to perforation of the gastrointestinal mucosa. Presenting symptoms include dysphagia, abdominal pain, substernal pain, diarrhea, and melena. It is important to distinguish IBD from Behçet's disease.[61] Oral aphthae, ocular lesions, erythema nodosum-like lesions, pustular vasculitis, and pyoderma gangrenosum can occur in patients with IBD.

Pulmonary abnormalities are uncommon in Behçet's disease. Pulmonary artery aneurysms occur most frequently, followed by other complications secondary to vasculitis that affect the small pulmonary vessels. Aneurysm, thrombosis, hemorrhage, and infarction can result and cause death in patients with Behçet's disease.[34]

Renal manifestations are not common. They range from minimal changes, to proliferative glomerulonephritis, to rapidly progressive crescentic glomerulonephritis. The pathogenesis is likely to involve immune complex deposition.[62] Aphthae may also affect the bladder.

Cardiovascular complications include myocardial infarction, pericarditis, arterial and venous thromboses, and aneurysm formation. Venous involvement is more common than arterial involvement: the most frequent manifestation is venous thrombosis in the lower extremities, although thromboses that cause superior and inferior vena cava obstruction can occur.[63] Hepatic vein thrombosis is a serious potential complication of Behcet's disease, which can lead to hepatic venous outflow obstruction and associated Budd-Chiari syndrome.[64] Cardiac manifestations, either occlusive or aneurysmal, are thought to occur because of vasculitis of the vasa vasorum, which induces a thickening of the media and splitting of elastic fibers.[65] Atherosclerosis does not appear to occur at an increased rate, as is seen in many autoimmune diseases such as systemic lupus erythematosus.[66] Mortality in Behçet's disease is low and is usually related to pulmonary or CNS involvement, or to bowel perforation.[9]

Limited data are available that evaluate Behçet's in pregnancy. One case-control study reported more remissions than exacerbations during and after pregnancy, with higher rates of pregnancy complications but no changes in neonatal outcomes.[67]

## HISTOPATHOLOGY

Histopathologic analysis of specimens from the cutaneous lesions seen in Behçet's disease reveals epidermal ulceration or pustule formation and diffuse dermal infiltrate of neutrophils, lymphocytes, and histiocytes, sometimes with fully developed leukocytoclastic vasculitis. Microscopic examination of dermal capillary or venule walls shows neutrophilic infiltrates, nuclear dust, and extravasation of erythrocytes, with or without fibrinoid necrosis.[68] Immune complex-mediated vasculitis is the likely mechanism in the development of Behçet's disease.[69] A previously reported finding of lymphocytic vasculitis in patients with Behçet's disease is thought to represent an older lesion.[48]

Biopsy specimens of synovial membranes reveal a neutrophilic reaction, with occasional plasma cells and lymphocytes. Immunofluorescence microscopy may show IgG deposition along the synovial membrane.[52] Reports of synovial fluid analysis in patients with Behçet's disease show leukocyte counts that range from 300 to 36,200 cells/mm$^3$, with a predominance of neutrophils and normal glucose levels.[55]

## DIAGNOSIS

The diagnosis of Behçet's disease can be difficult, particularly in patients with a limited number of common disease features. Clinicians and investigators must rely on clinical criteria because no pathognomonic laboratory findings exist. Several sets of diagnostic criteria have been proposed, including those by O'Duffy and Goldstein,[70] Mason and Barnes,[71] and a Japanese study group.[72] In 2008, the International Team for the Revision of International Criteria for Behçet's Disease revised the established criteria on the basis of the presence of various disease manifestations, including oral aphthae, cutaneous lesions, positive pathergy, genital aphthae, and ocular involvement.[73] Each manifestation contributes 1 or 2 points, and an individual with a score of 3 or more points is diagnosed with the disease (Table 93-1). A diagnostic algorithm based on the Revised International Criteria for Behçet's disease is presented in Figure 93-3.

**TABLE 93-1** Revised International Criteria for Behçet's Disease*

| | |
|---|---|
| Oral aphthosis | 1 point |
| Skin manifestations (pseudofolliculitis, skin aphthosis) | 1 point |
| Vascular lesions (phlebitis, large vein thrombosis, aneurysm, arterial thrombosis) | 1 point |
| Positive pathergy test | 1 point |
| Genital aphthosis | 2 points |
| Ocular lesions | 2 points |

*Diagnosis of Adamantiades-Behçet's disease is made with a score of 3 points.

Modified from International Team for the Revision of International Criteria for Behçet's Disease: Clinical manifestations of Behçet's disease. The ITR-ICBD report. *Clin Exp Rheumatol* 26(Suppl 50):S1–S18, 2008.

Although not required by diagnostic criteria, IBD, systemic lupus erythematosus, reactive arthritis, and herpetic infections should first be excluded because the presenting manifestations of these conditions are often similar to those of Behçet's disease. Recurrent aphthous stomatitis and complex aphthosis, defined as recurrent oral and genital aphthae or almost constant, multiple (three or more) oral aphthae, should also be considered in the differential diagnosis of patients presenting with oral or genital aphthae.[74]

The O'Duffy-Goldstein criteria mandate the presence of recurrent oral aphthae plus at least two of the following: genital aphthae, synovitis, posterior uveitis, cutaneous pustular vasculitis, and meningoencephalitis. Patients who have only two of these findings, one being recurrent oral aphthae, are considered to have an incomplete form of Behçet's disease. One concern with regard to the International Criteria for Behçet's is the inclusion of acneiform lesions, which are a common nonspecific finding in both adolescents and adults. Therefore, our group advocates histologic confirmation of vessel-based histology to exclude acne lesions and the use of both the O'Duffy and the International Study Group criteria to exclude patients with IBD and enteropathic arthritis.[75]

The initial evaluation should include a referral for ophthalmologic consultation to identify insidious ocular involvement. Patients who have arthralgias, gastrointestinal symptoms, or neurologic abnormalities may require radiographic studies and evaluation by appropriate subspecialists. Cutaneous pustular lesions, erythema nodosum-like lesions, and pyoderma gangrenosum-like lesions should be biopsied (for both histologic evaluation and culture) to confirm the cutaneous clinical diagnosis.

## TREATMENT

Treatment of Behçet's disease is largely based on anecdotal case reports, case series, and a few randomized clinical trials. Therapeutic options should be based on the degree of disease involvement (Tables 93-2 and 93-3).[46]

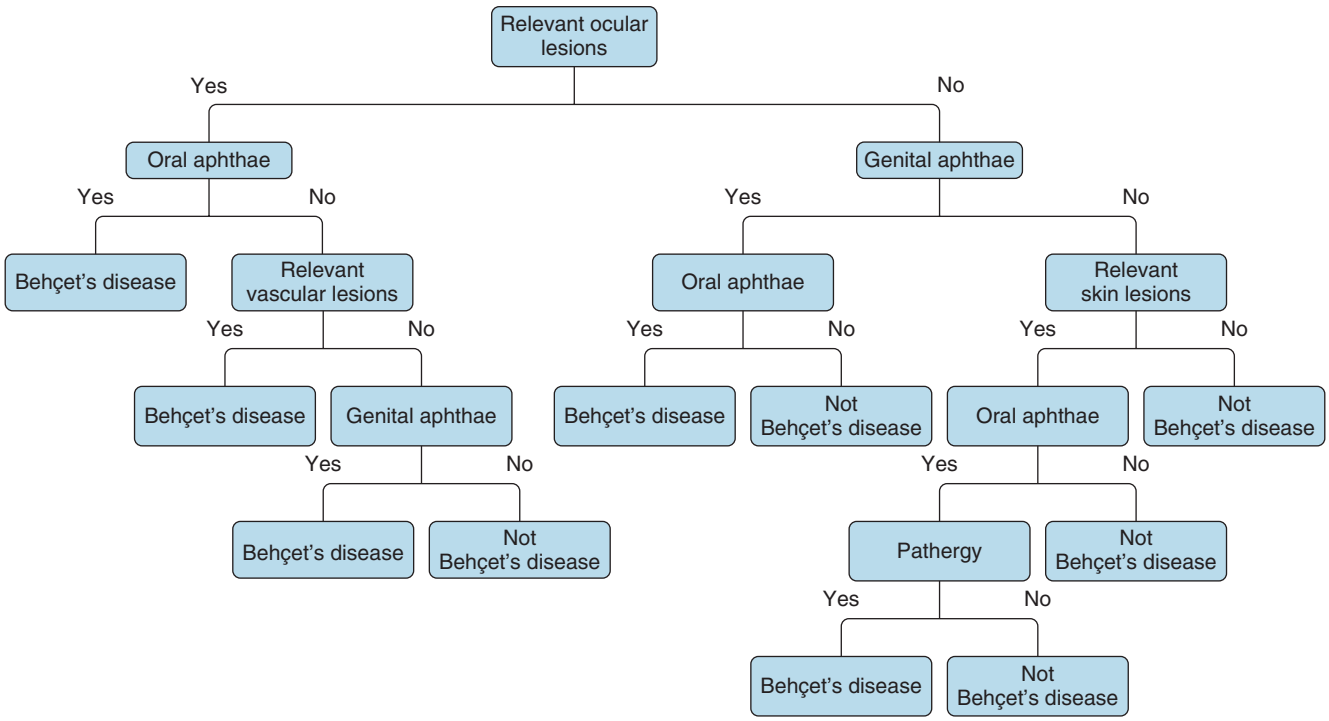

**Figure 93-3** Revised international criteria for Behçet's disease: diagnosis of Adamantiades-Behçet's disease. Classification tree format. *(Modified from International Team for the Revision of International Criteria for Behçet's Disease: clinical manifestations of Behçet's disease. The ITR-ICBD report.* Clin Exp Rheumatol *26[Suppl 50]:S1–S18, 2008.)*

**TABLE 93-2** Treatment of Behçet's Disease

| |
|---|
| **Mucocutaneous Disease Only**<br>Topical, intralesional, or aerosolized corticosteroids |
| Topical sucralfate |
| Local anesthetics |
| Topical tacrolimus |
| Colchicine (0.6-2.4 mg/day) |
| Dapsone (50-150 mg/day) |
| Combinations of agents mentioned above |
| **Severe Mucocutaneous Disease**<br>Thalidomide (50-300 mg/day) |
| Methotrexate (2.5-25 mg/wk) |
| Prednisone |
| IFN-α (3 million-9 million U/wk) |
| **Systemic Disease**<br>Prednisone |
| Azathioprine (50-200 mg twice daily) |
| Chlorambucil (4-6 mg/day) |
| Cyclophosphamide (1 g/mo, IV) |
| Cyclosporine (5-10 mg/kg/day) |
| Mycophenolate mofetil (500 mg-1.5 g, twice daily) |
| Intravenous (IV) immunoglobulin |
| Rituximab |
| TNF inhibitors |

## Mucocutaneous Disease

Patients with oral and genital aphthae can be treated with intralesional, topical, or aerosolized (not inhaled) corticosteroids. Topical tacrolimus can also be used, often in combination with superpotent topical corticosteroids. Other palliative therapies include oral tetracycline solutions, topical anesthetics, and rinses containing chlorhexidine gluconate. Oral colchicine, 0.6 to 2.4 mg daily, can decrease the size and frequency of mucocutaneous lesions.[76,77] Doses can be adjusted according to the degree of gastrointestinal upset experienced by the patient. Dapsone in a dose of 50 to 150 mg/day is often helpful alone[78] or in combination with colchicine.[74] Physicians should check glucose-6-phosphate dehydrogenase levels in all patients before beginning therapy with dapsone, and patients must be monitored for hemolytic anemia and methemoglobinemia. TNF inhibitors also improve mucosal and skin manifestations of Behçet's disease.[79,80] The oral phosphodiesterase-4 inhibitor apremilast has recently been found to decrease the number and pain of oral ulcers, in addition to improving overall disease activity.[81]

## Severe Mucocutaneous Disease

Patients in whom conservative therapies fail to produce the desired response as outlined for mucocutaneous disease may require thalidomide. Its mechanism of action is thought to be mediated by modulation of TNF and other cytokines. Previous studies have shown that thalidomide is an effective agent for the treatment of severe mucocutaneous lesions of Behçet's disease.[82,83,84] Thalidomide is known to cause severe

**TABLE 93-3** Modified EULAR 2008 Recommendations for the Management of Behçet's Disease (BD)

| No. | Recommendation |
|---|---|
| 1 | Any patient with BD and inflammatory eye disease affecting the posterior segment should be on a treatment regimen that includes azathioprine *or mycophenolate** and systemic corticosteroids. |
| 2 | If the patient has severe eye disease defined as >2 lines of drop in visual acuity on a 10/10 scale and/or retinal disease (retinal vasculitis or macular involvement), it is recommended that either cyclosporine A or infliximab be used in combination with azathioprine and corticosteroids; alternatively, IFN-α with or without corticosteroids could be used instead. |
| 3 | There is no firm evidence to guide the management of major vessel disease in BD. For the management of acute deep vein thrombosis in BD immunosuppressive agents such as corticosteroids, azathioprine, cyclophosphamide, or cyclosporine A are recommended. For the management of pulmonary and peripheral arterial aneurysms, cyclophosphamide and corticosteroids are recommended. |
| 4 | Similarly, there are no controlled data on, or evidence of benefit from, uncontrolled experience with anti-coagulants, anti-platelet, or antifibrinolytic agents in the management of deep vein thrombosis or for the use of anticoagulation for the arterial lesions of BD. |
| 5 | There is no evidence-based treatment that can be recommended for the management of gastrointestinal involvement of BD. Agents such as sulfasalazine, corticosteroids, azathioprine, TNF antagonists, and thalidomide should be tried first before surgery, except in emergencies. |
| 6 | In most patients with BD, arthritis can be managed with colchicine. |
| 7 | There are no controlled data to guide the management of CNS involvement in BD. For parenchymal involvement, agents to be tried may include corticosteroids, IFN-α, azathioprine, cyclophosphamide, methotrexate, and TNF antagonists. For dural sinus thrombosis corticosteroids are recommended. |
| 8 | Cyclosporine A should not be used in BD patients with CNS involvement unless necessary for intraocular inflammation. |
| 9 | The decision to treat skin and mucosa involvement will depend on the perceived severity by the doctor and the patient. Mucocutaneous involvement should be treated according to the dominant or codominant lesions present. Topical measures (i.e., local corticosteroids) should be the first line of treatment for isolated oral and genital ulcers. Colchicine should be preferred when the dominant lesion is erythema nodosum. *Dapsone may also be used.* Leg ulcers in BD might have different causes. Treatment should be planned accordingly. *Thalidomide*, azathioprine, IFN-α, and TNF antagonists may be considered in resistant cases. |

*The authors' modifications to the recommendations are noted in italics.
BD, Behçet's Disease; CNS, central nervous system; EULAR, European League Against Rheumatism; IFN-α, interferon-alpha; TNF, tumor necrosis factor.
From Hatemi G, Silman A, Bang D, et al: EULAR recommendations for the management of Behçet disease. *Ann Rheum Dis* 67:1656, 2008.

birth defects, and all patients and prescribing physicians must adhere to the System for Thalidomide Education and Prescribing Safety (STEPS) protocol, including monthly follow-up visits.[85] Patients receiving thalidomide can be monitored with nerve conduction studies for the development of peripheral symmetrical sensory neuropathy, if such monitoring is warranted on the basis of the clinical neurologic evaluation. Notably, the cost of treatment increased drastically when thalidomide was approved for the treatment of multiple myeloma.

Low-dose oral methotrexate (2.5 to 25 mg/wk) and low-dose prednisone are alternatives for patients with severe mucocutaneous involvement.[86] Patients receiving methotrexate should be monitored for hepatotoxicity and leukopenia. The risk of rebound after the tapering or discontinuation of systemic prednisone greatly limits its use for mucocutaneous disease alone. In addition, IFN-α is effective for severe mucocutaneous lesions and some systemic manifestations.[87,88] A review of the safety and efficacy of IFN-α by Zouboulis and Orfanos[87] recommended a 3-month, high-dose regimen of 9 million units three times per week, followed by a low, maintenance dose of 3 million units, three times per week. Patients experience the usual flulike symptoms associated with this therapy.

## Systemic Disease

Patients with systemic disease such as ocular and cardiovascular abnormalities require immunosuppressive therapy, particularly in view of the risk of morbidity and mortality resulting from untreated disease. Systemic corticosteroids may be used alone or in combination with other immunosuppressive agents such as azathioprine, IFN-α, cyclosporine, cyclophosphamide, and chlorambucil.[89] The standard of care for eye disease is prednisone plus azathioprine.[90] If this combination is not successful, one of the aforementioned immunosuppressive agents or mycophenolate mofetil can be substituted for azathioprine.[89] Rituximab has also been effective in the treatment of severe ocular manifestations of Behçet's disease.[80] Several of these immunosuppressive agents have associated hematologic toxicity, as well as the potential for the development of associated malignancies; therefore, close monitoring is essential. There have also been reports of Behçet's disease treated with anti-TNF agents.[91] A double-blind, placebo-controlled trial showed that etanercept was successful in suppressing most of the mucocutaneous manifestations of Behçet's disease.[92] Other reports support the efficacy of adalimumab and infliximab.[93,94,95] In 2008, the European League Against Rheumatism (EULAR) developed a standard of recommendations for the management of the various systemic manifestations of Behçet's disease (see Table 93-3).

# OUTCOME

Behçet's disease has a variable clinical course in most patients with a pattern of exacerbations and remissions. A delay in diagnosis after the initial manifestation of Behçet's disease is common. Most patients present initially with mucocutaneous manifestations, and evidence of ocular and neurologic involvement may appear several years after diagnosis. Patients with the finding of complex aphthosis may

represent a *forme fruste* of Behçet's disease, and they should be monitored for the development of additional abnormalities fulfilling the diagnostic criteria through regular follow-up and referral to appropriate specialists.[74] The greatest morbidity is associated with ocular manifestations (two-thirds of patients), vascular disease (one-third of patients), and CNS disease (10% to 20% of patients).[96] Ocular involvement is the most common cause of morbidity primarily manifesting as posterior uveitis and retinal vasculitis which can result in blindness. Mortality in Behçet's disease is low and is usually related to pulmonary or CNS involvement or to bowel perforation.[9]

CHAPTER 94

# Etiology and Pathogenesis of Hyperuricemia and Gout

Robert T. Keenan • Svetlana Krasnokutsky • Michael H. Pillinger

**KEY POINTS**

- Uric acid is the biologically active end product of human purine metabolism.
- Serum urate concentrations are determined by the balance between urate production and elimination; hyperuricemia results from urate overproduction, urate under excretion, or a combination of both.
- Specific organic anion transporters play a central role in urate excretion by the kidney.
- Hyperuricemia is defined as serum urate levels greater than 6.8 mg/dL, the limit of its solubility in serum.
- Gout pathogenesis requires the accumulation of monosodium urate at levels sufficient to drive the precipitation of crystals.
- Monosodium urate crystals drive inflammatory responses, including activation of the NLRP3 inflammasome, a multimolecular cytosolic complex that processes and generates IL-1β.
- The initiation of gouty inflammation by local leukocytes induces an influx of neutrophils into the joint; when neutrophils encounter urate crystals, they become activated and propagate further inflammation.
- Inflammation persists in chronic and tophaceous gout; macrophages continue to produce cytokines and proteases, thereby facilitating cartilage and bone destruction.

The ancient disease *gout* has a complex pathogenesis, and its modern relevance is underscored by a rise in prevalence by as much as fourfold in the past half century. Indeed, gout is now the most common inflammatory arthritis in the United States.[1,2] Gout is a disease of both metabolism and inflammation. Gout pathogenesis requires the intersection of two distinct processes: (1) the intrinsic formation of uric acid, in the form of urate, at levels sufficient to drive the precipitation of monosodium urate into crystallized forms, and (2) an inflammatory response to the crystals formed in this manner. How these processes occur and the circumstances under which they cross from adaptive to pathologic responses are the subjects of this chapter.

## EVOLUTIONARY CONSIDERATIONS

**KEY POINT**

- High baseline levels of serum urate in humans may be the result of evolutionary pressures in a prior era when hyperuricemia provided survival benefits.

The metabolic production of uric acid is ubiquitous among mammals and many other forms of animal life, and it is important to recognize that urate generation is not *a priori* pathologic. Indeed, the production of uric acid may serve one or possibly a multitude of beneficial roles, an area of interest to molecular immunologists and molecular anthropologists alike.

### Uric Acid as a Danger Signal

Uric acid is a breakdown product of purine metabolism. As such, it represents a metabolic waste molecule that might, in theory, be nothing more than a nuisance requiring excretion. However, evolution has co-opted this waste-generating process to play an important and perhaps critical role in organismal immunity. It has long been appreciated that the lysates of damaged mammalian cells can serve effectively as adjuvants—that is, they can promote immune responses to injected antigens. Recently Shi et al[3] used classic biochemical techniques to demonstrate that the major endogenous adjuvant found in damaged cells was uric acid. These investigators further demonstrated that uric acid has the capacity to promote T cell activation in response to antigen and that aggressive urate-lowering treatment could abrogate murine immune responses. Thus uric acid may serve as a *danger signal* to promote immune responses. As first proposed by Matzinger,[4] a danger signal is an intrinsically produced molecule, typically issued by an altered or damaged cell to alert the immune system to the need for an immunologic response. Viewed from this perspective, the production of uric acid in a virally infected cell, for example, might serve as an

Video available on the accompanying ExpertConsult website.

upstream "second signal" to promote antigen presentation by professional antigen-presenting cells such as dendritic cells, macrophages, or B cells. Indeed, although damaged or dying cells tend to have limited ability to manufacture proteins, their output of uric acid characteristically increases during cellular breakdown. The uric acid danger signal might also play an important role in tumor immunity, and at least one mouse model suggests that modulation of uric acid levels may directly affect immune tumor rejection.[5] Although these observations require more study, they are consistent with a paradigm in which urate production at the local cellular level may play an important role in immunity and homeostasis.

## Uric Acid and Human Evolution

Most mammals have serum urate levels in a range roughly between 0.5 and 2 mg/dL. In contrast, humans and other primates, including great apes and some New World monkeys, typically demonstrate serum urate levels between 4 and 6 mg/dL. The genetic and biochemical basis for these increases is well appreciated. During the Miocene era (10 to 25 million years ago), mutations in various primate species resulted in inactivation of the uricase gene, which codes for the enzyme that degrades uric acid to allantoic acid. Genetic studies indicate that the uricase gene underwent nonsense and other mutations not once but multiple times, across multiple hominoid lineages (Figure 94-1).[6-8] The occurrence of multiple independent loss-of-function mutations has led some biologists to hypothesize that increases in urate generation may have conferred a survival benefit for these particular species. Several compelling and not necessarily mutually exclusive hypotheses have been proposed.

These same primate species had also been subject to a unique deletion of the gene permitting organisms to produce ascorbic acid, an event that occurred in the Eocene era, 10 to 20 million years before the uricase deletions.[9] In mammals that produce it, ascorbic acid serves as the pre-eminent antioxidant in the body. Thus the loss of ascorbate production may have created an evolutionary liability, for which increases in urate provided antioxidant compensation. Other authors have suggested that the effects of hyperuricemia provided an evolutionary advantage by promoting hominoid intellectual function, either through its antioxidant effects or via activation of neurostimulatory adenosine receptors (in a manner similar to that of caffeine).[10] Although the antioxidant theory would appear compelling, critics have pointed out that (1) the production of urate itself generates oxidant molecules, diminishing any possible antioxidant benefit; (2) intra-cellular urate may have pro-oxidant effects[11]; and (3) the human/primate capacity for antioxidation may be large even in the absence of soluble antioxidants (e.g., human red blood cell membranes have extensive antioxidant capacities).[12]

Other investigators have examined the specific evolutionary pressures exerted on primate species during the Miocene era in an attempt to understand the potential advantages of urate elevations. Johnson and colleagues[13] pointed out that rapid hominoid evolution occurred during the Miocene era and that the hominoid diet at that time appears to have been mainly vegetarian and extremely low in salt. These investigators suggest that hominoids during that period may have experienced a "hypotensive crisis," particularly in the face of the transition to upright walking. They further postulate that an elevation in serum uric acid levels provided a mechanism for restoring normotension, primarily through urate-induced renovascular injury.[13,14] To model this hypothesis, these investigators exposed rats to a low-salt diet, resulting in hypotension. When treated with the uricase inhibitor oxonic acid (to mimic the primate uricase loss), the rats' urate levels rose and their blood pressures normalized. The effects of uricase inhibition on blood pressure could be reversed through the use of the urate-lowering agent allopurinol. These observations imply that what may once have been a homeostatic adaptation could now contribute to essential hypertension in today's salt-rich era. In support of the latter hypothesis, Feig and colleagues[15] identified adolescents with premature essential hypertension and hyperuricemia and treated them with the urate-lowering agent allopurinol. The result was normalization in blood pressure that reversed after allopurinol discontinuation. More recent studies have implicated elevated levels of uric acid as having a possible role in increased gluconeogenesis, with potential metabolic benefit in the Miocene era (which was also calorie poor), but perhaps contributing to the incidence of diabetes in our current calorie-rich environment.[16,17]

Although the loss of uricase promoted serum urate increases in humans and other hominoids, the levels of serum urate so achieved are generally insufficient to promote urate crystallization and gout. Rather, uricase inactivation created the circumstances under which additional increases in urate production, or impairments in urate excretion, can result in serum urate concentrations exceeding the solubility threshold. Accordingly, we next review the mechanisms of urate production and excretion, as well as the events that may tip the scales toward pathologic hyperuricemia.

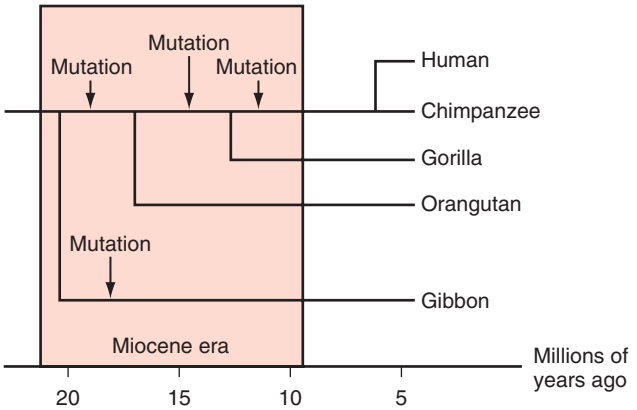

**Figure 94-1** Mutations affecting the uricase gene. During the Miocene era, hominoid species experienced not one but multiple different mutations, resulting in the loss of uricase activity. The survival of multiple species harboring different mutations suggests that loss of uricase may have conveyed a survival advantage, even as it established the necessary precondition for hyperuricemia and gout. *(Modified with permission from Wu XW, Muzny DM, Lee CC, Caskey CT: Two independent mutational events in the loss of urate oxidase during hominoid evolution,* J Mol Evol *34:78–84, 1992. Copyright Springer-Verlag GmbH.)*

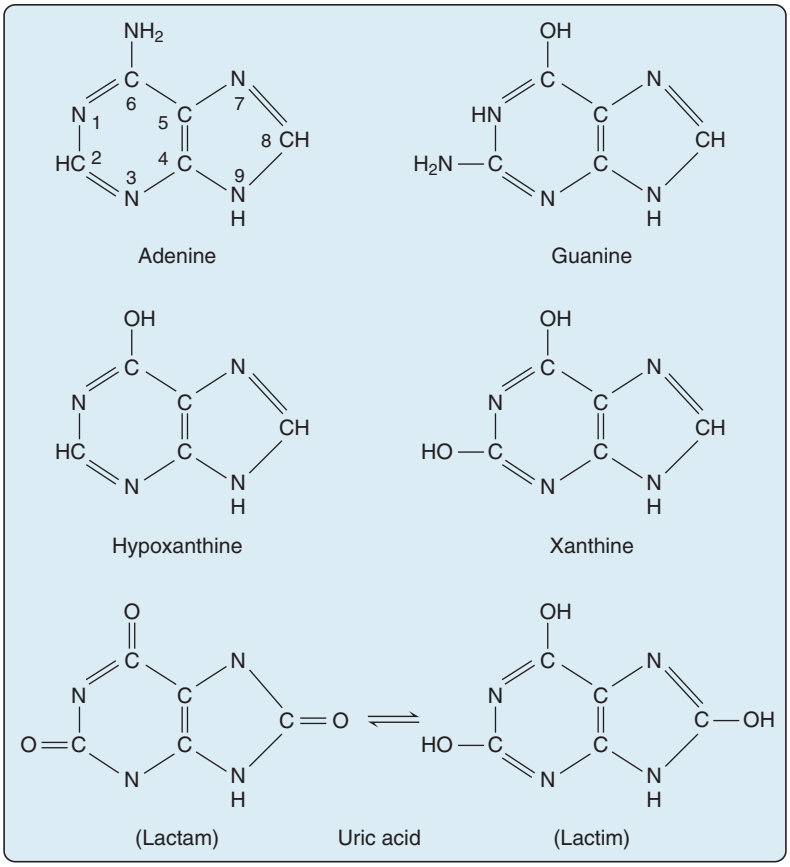

**Figure 94-2** Structure of uric acid and common purines. All purine bases may exist in the lactam form in a reversible manner as shown for uric acid.

## URIC ACID PRODUCTION AND EXCRETION: NORMAL LEVELS AND HYPERURICEMIA

Uric acid is a breakdown product of purines, and uric acid generation depends directly on both intrinsic purine production and purine intake. In humans, uric acid is an end-product metabolite; consequently, the depletion of uric acid depends directly on its excretion. The balance between uric acid production and excretion determines the serum urate level. Most people maintain a relatively stable uric acid level between 4 and 6.8 mg/dL and a total body uric acid pool of approximately 1000 mg.[18] Persons with serum uric acid levels greater than 6.8 mg/dL, even without clinical gout, may deposit uric acid crystals either occultly or in the form of appreciable masses (tophi), with the consequence that the total body urate pool may be significantly higher than in persons who are not hyperuricemic.[19,20] Such occult deposition of uric acid (the total body urate burden) may have implications for treatment because it may form a "buffering reservoir" of urate that resists initial treatment with urate-lowering agents.

### Urate Production: Purine Metabolism and Intake

**KEY POINT**

**Uric acid is the end product of human purine metabolism.**

Uric acid production depends on both purine biosynthesis and the metabolic processes that convert purines into uric acid.

#### Purine Biosynthesis

Purines are heterocyclic aromatic compounds consisting of conjoined pyrimidine and imidazole rings (Figure 94-2). In mammals, the most common expression of purines is found in the form of DNA and RNA (containing the purines adenine and guanine), as well as single-molecule nucleotides (adenosine triphosphate [ATP], adenosine diphosphate [ADP], adenosine monophosphate [AMP], cyclic AMP, and to a lesser extent, guanosine triphosphate [GTP] and cyclic guanosine monophosphate [cGMP]). Purines are also critical elements of the following energy metabolism molecules: reduced nicotinamide adenine dinucleotide, nicotinamide adenine dinucleotide phosphate (NADPH), and coenzyme Q. Purines may also serve as direct neurotransmitters; for example, adenosine may interact with receptors to modulate cardiovascular and central nervous system (CNS) function.[21]

Purine biosynthesis is initiated on a backbone of ribose-5-phosphate (Figures 94-3 and 94-4). The enzyme phosphoribosyl pyrophosphate (PRPP) synthase catalyzes the addition of a pyrophosphate moiety to form the adduct PRPP. This reaction is thought to be rate limiting. Subsequently, the enzyme glutamine-PRPP amidotransferase catalyzes the interaction of PRPP and glutamine to form

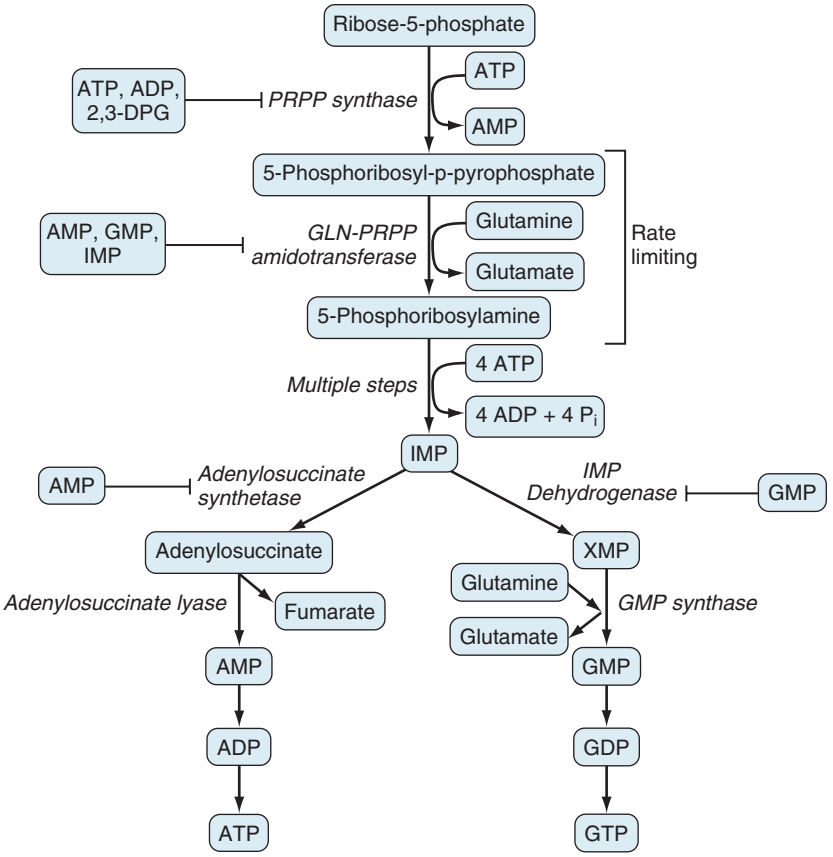

**Figure 94-3** Purine biosynthesis (see text for details). ADP, Adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate; 2,3-DPG, 2,3-diphosphoglycerate; GDP, guanosine diphosphate; GLN, glutamine; GMP, guanosine monophosphate; GTP, guanosine triphosphate; IMP, inosine monophosphate; PRPP, phosphoribosyl pyrophosphate; XMP, xanthine monophosphate.

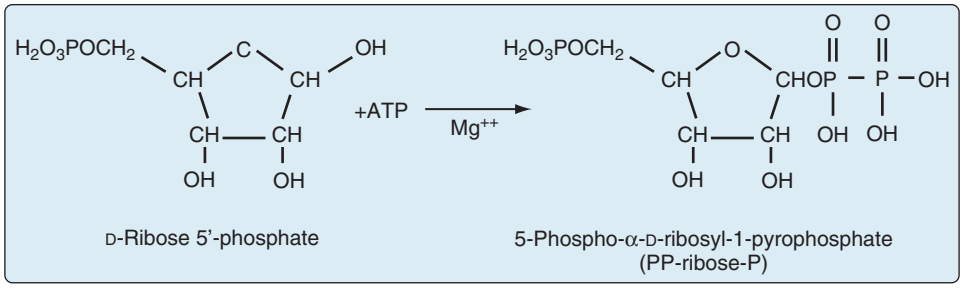

**Figure 94-4** Formation of phosphoribosyl pyrophosphate by phosphoribosyl pyrophosphate synthase. In some patients, this reaction proceeds too rapidly, promoting hyperuricemia on the basis of primary overproduction of uric acid.

5-phosphoribosyl amine, the first committed step in purine biosynthesis; 5-phosphoribosyl amine next serves as the backbone for a series of molecular additions, ending in the formation of the purine inosine monophosphate (IMP). IMP is converted into either AMP or GMP, which can then be phosphorylated into higher energy compounds (e.g., ATP and GTP). Glutamine-PRPP amidotransferase and PRPP synthase are both subject to feedback inhibition by purines themselves, providing a mechanism to slow purine biosynthesis in the setting of purine sufficiency. Collectively, the process of purine biosynthesis is highly energy dependent, requiring the consumption of multiple molecules of ATP. Thus purine biosynthesis not only directly increases the substrate load for urate generation but also increases the turnover of already formed purines that contribute to increased urate levels.[22]

## Urate Formation and Purine Salvage

Purines generated by the previously described mechanisms are susceptible to enzymatic catabolism, presumably to maintain purine homeostasis (Figure 94-5). Purines susceptible to degradation include the monophosphate nucleotides GMP and IMP. These molecules are converted by nucleotidases to their purine base forms, guanosine and inosine. In contrast to GMP and IMP, AMP is not susceptible to nucleotidase activity. However, through the activity of adenylate deaminase, AMP can undergo conversion into IMP for further degradation. Additionally, adenosine deaminase can convert adenosine to inosine for inclusion in the degradative pathway. Further catabolism of both guanosine and inosine is mediated by the common enzyme purine nucleoside phosphorylase. Guanosine is converted to

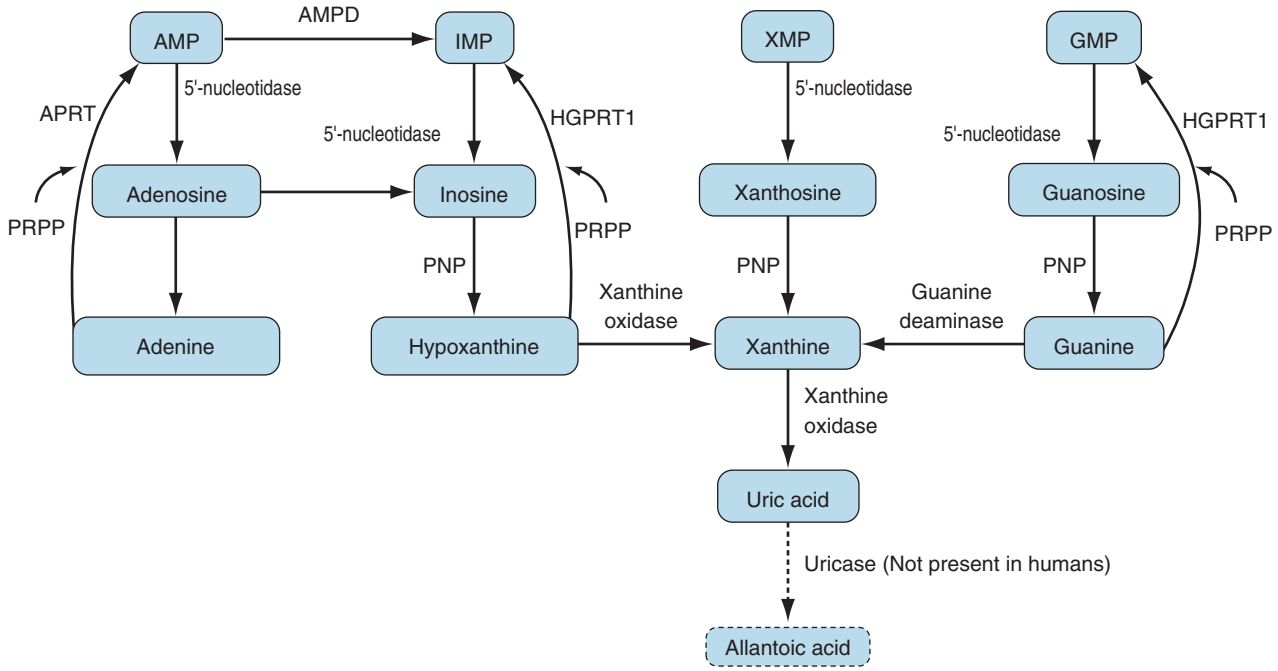

**Figure 94-5** Uric acid synthesis and purine salvage. Catabolism of purines, especially inosine monophosphate (IMP) and guanosine monophosphate (GMP), results in urate synthesis via the common substrate xanthine. Xanthine oxidase is necessary for urate synthesis from any purine and thus serves as a target for agents that inhibit uric acid synthesis (e.g., allopurinol and febuxostat). Purine salvage via hypoxanthine guanine phosphoribosyl transferase 1 (HGPRT1) returns hypoxanthine and guanine to IMP and GMP, respectively. HGPRT1 deficiencies result not only in increases in hypoxanthine and guanine and subsequent uric acid synthesis but also in the depletion of nucleotides that provide feedback inhibition on purine biosynthesis. As denoted in *gray,* mammals other than primates and some monkeys possess uricase, which converts uric acid to allantoic acid for further degradation. AMP, Adenosine monophosphate; AMPD, AMP deaminase; APRT, adenine phosphoribosyl transferase; PNP, purine nucleotide phosphorylase; PRPP, phosphoribosyl pyrophosphate; XMP, xanthine monophosphate.

guanine, whereas inosine is converted to hypoxanthine. Both guanine and hypoxanthine are subsequently converted to xanthine by the enzymes guanine deaminase and xanthine oxidase (also known as *xanthine dehydrogenase*), respectively. Xanthine from either source is then converted directly to uric acid, again by the action of xanthine oxidase. As previously noted, organisms other than humans and primates, including New World monkeys, possess an additional enzyme, uricase (urate oxidase), that converts uric acid to allantoic acid, a relatively soluble compound that can be further degraded to urea. Because of the lack of this enzyme, human and primate purine metabolism ceases with the production of uric acid.[23]

Presumably because purine synthesis is energy expensive for the cell, evolution has dictated that mechanisms exist to recover purines before they irreversibly traverse the degradative pathway. These pathways, collectively known as *purine salvage*, are intimately connected to the feedback regulation of purine synthesis. The major enzyme responsible for purine salvage, hypoxanthine/guanine phosphoribosyl transferase (HGPRT1, also known as HPRT1), catalyzes the transfer of a phosphoribose from PRPP to either hypoxanthine or guanine to form IMP or GMP, respectively (Figure 94-6). These products are then available for reinclusion in the available purine pool. A second salvage enzyme is adenine phosphoribosyl transferase, which restores adenine to AMP. However, as described earlier, most adenosine/adenine breakdown occurs via conversion to inosinic acid.

## Urate Overproduction: Primary and Secondary Causes

**KEY POINT**

**Hyperuricemia may result from urate overproduction as a result of primary or secondary causes.**

### Primary Urate Overproduction

In some patients, inborn errors of metabolism lead to urate overproduction and subsequent hyperuricemia. Several of these inborn errors of metabolism deserve mention. First, a small number of persons possess PRPP synthase enzymes that are hyperactive. The result is increased generation of PRPP. Because under normal circumstances PRPP concentrations are below the Michaelis constant of glutamine-PRPP amidotransferase for this substrate, increased PRPP levels drive amidotransferase activity and accelerate purine biosynthesis.

The second well-described class of abnormality leading to urate overproduction occurs within the purine salvage pathway. Deficiencies of HGPRT1 result in impaired purine salvage and increased substrate for uric acid generation. Additionally, because purine salvage normally results in nucleotide monophosphate generation, patients with purine salvage failure experience lower levels of nucleotide monophosphates, resulting in loss of feedback inhibition of both PRPP synthase and glutamine-PRPP amidotransferase.

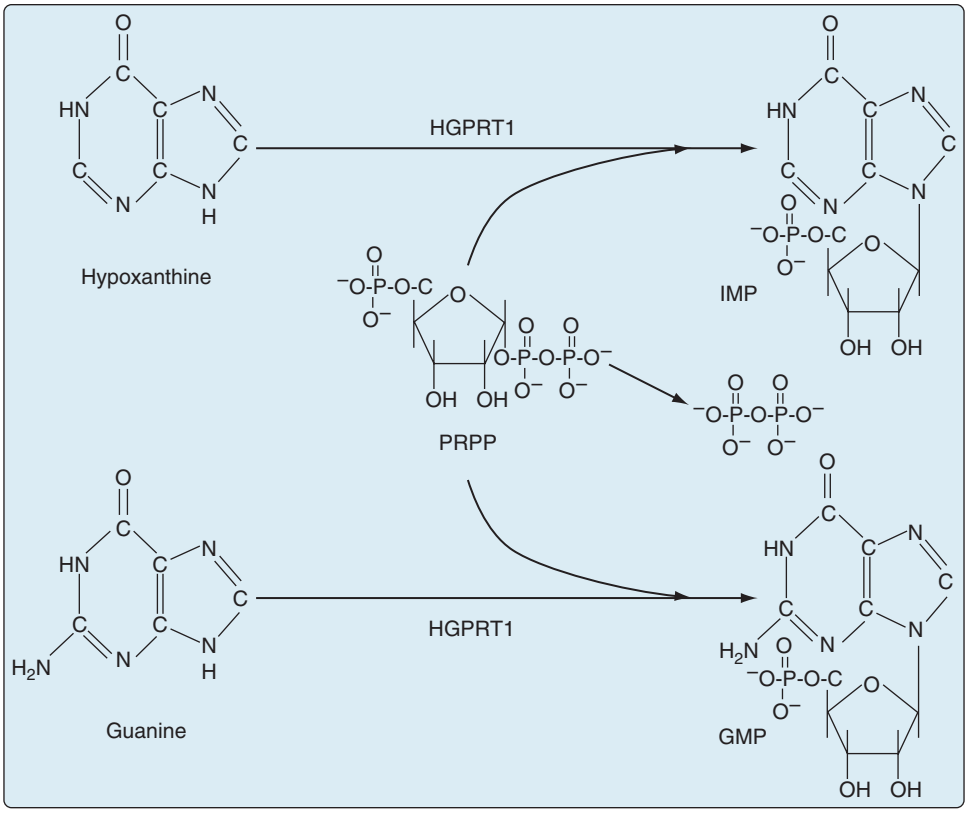

**Figure 94-6** Actions of hypoxanthine/guanine phosphoribosyl transferase 1 (HGPRT1) result in salvage of hypoxanthine and guanine to inosine monophosphate (IMP) and guanosine monophosphate (GMP). Loss of HGPRT1 activity results in hyperuricemia and, in severe cases, the neurologic deficits of Lesch-Nyhan syndrome. PRPP, Phosphoribosyl pyrophosphate.

Thus purine salvage failure resulting from HGPRT1 deficiency is compounded by purine overproduction. Recent studies have identified mutations in *ALDH16A1* (a member of the aldehyde dehydrogenase superfamily) that may promote gout by impairing the function of HGPRT1.[24]

Two major variants of HGPRT1 deficiency have been described. Complete HGPRT1 deficiency, better known as *Lesch-Nyhan syndrome*, is an X-linked recessive disorder characterized by extremely high levels of serum urate, gout flares, nephrolithiasis, mental retardation, movement disorders, and behavioral disorders, including self-mutilation. The disorder can occasionally arise by de novo mutation; female carriers are generally asymptomatic but may have elevated serum urate levels. In contrast to the gout flares and nephrolithiasis, the neurologic findings in Lesch-Nyhan syndrome are independent of hyperuricemia and unresponsive to urate-lowering drugs. Life expectancy can be greatly reduced, and these patients rarely come to the attention of adult rheumatologists.[25]

In contrast to people with Lesch-Nyhan syndrome, persons with Kelley-Seegmiller syndrome have a partial deficiency of HGPRT1[26]; they present with hyperuricemia and gout but have limited or no neurologic symptoms.[27] Several variants of Kelley-Seegmiller syndrome have been described, based on the extent of HGPRT1 inactivity and the presence or absence of neurologic findings. Kelley-Seegmiller mutations tend to occur in regions of the *HPRT1* gene other than the regions identified in persons with Lesch-Nyhan syndrome (whose mutations typically localize to the PRPP-binding region); whether such differences influence the presence or absence of neurologic symptoms has not been determined.[28]

Several hereditary defects of energy metabolism also promote hyperuricemia, mainly as a consequence of ATP consumption. Persons with glucose-6-phosphatase deficiency (type I glycogen storage, or von Gierke's disease) demonstrate a high rate of both purine and ATP turnover. The lactic acidemia that secondarily occurs in patients with glucose-6-phosphatase deficiency may also contribute to hyperuricemia by promoting decreased renal urate excretion (discussed in a subsequent section).[29] Persons with fructose-1-phosphate aldolase deficiency lack the capacity to metabolize fructose-1-phosphate. Fructose-1-phosphate accumulation causes feedback inhibition of fructokinase and fructose accumulation in the blood. As an apparent consequence of these changes, AMP accumulates and promotes hyperuricemia by the mechanisms previously described.[30] The role of fructose intake in patients without inborn errors of fructose metabolism is discussed in a subsequent section.

## Secondary Urate Overproduction and Hyperuricemia

A number of secondary causes can lead to urate overproduction and hyperuricemia. In most cases, these conditions induce increased cell turnover, with resultant purine

generation and breakdown. Chief among these must be counted diseases of erythropoietic, lymphopoietic, and myelopoietic cell turnover of both malignant and nonmalignant varieties. Among the erythropoietic diseases causing hyperuricemia, autoimmune and other hemolytic anemias (i.e., red blood cell destruction with compensatory increased red blood cell generation), sickle cell disease,[31,32] polycythemia vera,[33] and ineffective erythropoiesis (e.g., in pernicious and other forms of megaloblastic anemia, thalassemia, and other hemoglobinopathies) must be included. Patients with myeloproliferative and lymphoproliferative disorders including myelodysplastic syndrome, myeloid metaplasia, leukemias, lymphomas, and paraproteinemic diseases such as multiple myeloma and Waldenström's macroglobulinemia are also at increased risk for hyperuricemia.[34-36] In some cases, particularly in the pediatric setting, hyperuricemia and concomitant renal failure may be the first presentation of these malignancies.[37] Indeed, the level of hyperuricemia may correlate with the degree of disease and cell turnover. Patients with essential thrombocytosis may also be at increased risk for hyperuricemia.[38] An association between solid tumors and hyperuricemia has been reported[39]; given the slower turnover of solid tumor cells, solid tumor hyperuricemia tends to be less common and less severe than that seen in malignancies of bone marrow–derived cells.

Tumor lysis syndrome represents a unique form of tumor-related hyperuricemia in which cell death induced by chemotherapy not only results in hyperuricemia but also hyperphosphatemia, hyperkalemia, and hypocalcemia, often resulting in acute renal failure and arrhythmias. Although tumor lysis syndrome occurs most commonly during treatment for hematologic malignancies,[40] it also may occur during treatment of solid tumors.[41,42] Although not well documented in the literature, we have noted hyperuricemia subsequent to the use of granulocyte colony-stimulating factor (G-CSF) for myelofibrosis-associated anemia. Such use of CSFs may secondarily contribute to the new onset of gout.[43]

Although somewhat more controversial, the increased cell turnover in patients with psoriasis has also been associated with elevated levels of serum urate.[44,45] An association between sarcoidosis and hyperuricemia has also been proposed,[46] again presumably relating to increased cell turnover and/or metabolic activity. However, the epidemiologic evidence supporting sarcoidosis as a cause of hyperuricemia is less than convincing.

Conditions leading directly to the physiologic consumption/degradation of ATP also contribute to the potential for secondary purine turnover leading to hyperuricemia. Thus strenuous and prolonged exercise, particularly to levels driving anaerobic respiration, may induce transient serum urate elevations.[47,48] *Status epilepticus* is likely to mimic these events. A number of acute illnesses, including myocardial infarction and sepsis, are also accompanied by ATP catabolism and may result in transient hyperuricemia.[49] Patients with hereditary myopathies including metabolic myopathies such as glycogen storage disease types III, V, and VII (debranching enzyme deficiency, myophosphorylase deficiency, and muscle phosphofructokinase deficiency, respectively), as well as mitochondrial myopathies (including carnitine palmitoyltransferase deficiency and myoadenylate deaminase deficiency), are susceptible to increases in serum urate levels after even moderate exercise.[39,49,50] In these persons, a limited ability to synthesize ATP on demand apparently results in a rapid turnover of established ATP pools during exercise, with resultant purine and uric acid formation. Patients with medium-chain acyl-coenzyme A dehydrogenase deficiency, a defect of fatty acid metabolism, also have been shown to have elevated levels of serum urate, although the mechanism for this effect is not clear.[51]

Despite multiple potential mechanisms, abnormalities of urate overproduction account for only about 10% of patients with hyperuricemia.

## Urate Excretion: Gastrointestinal and Renal Mechanisms

**KEY POINT**

**Urate excretion occurs via the gut and the kidneys. In the kidneys, a complex series of urate transport proteins mediates a net elimination of sodium urate.**

In most patients, the serum urate level is maintained within a narrow range. Accordingly, mechanisms must exist to ensure disposal of urate, either by metabolism or excretion. As previously noted, humans possess minimal or no capacity to metabolize urate; therefore, urate excretory mechanisms play a critical role in homeostasis. The gastrointestinal tract and the kidneys each participate in urate excretion.

### Gastrointestinal Excretion of Urate

Uric acid elimination via the gastrointestinal tract has been recognized for more than 50 years but has been the subject of relatively little study. On the basis of radiolabeled urate tracer studies, Sorensen and Levinson[52-54] estimated that in healthy persons, the gastrointestinal tract is responsible for the excretion of 20% to 30% of the daily uric acid burden. Gastrointestinal uric acid excretion may become more important in settings of renal insufficiency, however, in view of animal studies suggesting that uric acid excretion via the gut may increase in a compensatory manner in the setting of renal failure and decreased renal uric acid excretion.[55] Mechanisms of uric acid transport into the gut appear to include both exocrine secretion (e.g., saliva, gastric, and pancreatic juices) and direct bowel secretory mechanisms and appear to involve a urate transporter known as ATP-binding cassette transporter G2 (ABCG2), which also plays a role in renal urate excretion (discussed in a subsequent section).[39,56] Uric acid is apparently excreted into the gut in its native form and then undergoes degradation by intestinal flora.[54]

### Renal Excretion of Uric Acid: Normal Mechanisms

In all but the most extreme circumstances of renal failure, the kidney is the primary organ for uric acid excretion. The mechanisms of renal urate excretion are complex and involve multiple steps. In the bloodstream, uric acid (in the form of urate anion) is considered to be completely or nearly completely unbound to plasma proteins. As a result, nearly 100% of the urate load entering the renal afferent arteriole

undergoes ultrafiltration by the glomerulus. As discussed further in a subsequent section, decreases in glomerular function therefore reduce urate filtration and promote increases in serum urate levels.

After ultrafiltration, urate (initially in a monovalent ion form) in the proximal tubule undergoes distinct but apparently simultaneous handling steps: (1) a *resorption step*, in which as much as 90% to 98% of the filtered urate undergoes reclamation; and (2) a *secretion step*, in which resorbed urate is transferred back into the tubule lumen. The net result is excretion of approximately 10% of the filtered load. In fully functioning nephrons, these steps are responsive to serum urate levels, such that rises in serum urate induce increased renal excretion and restoration of total body urate homeostasis. Studies have emphasized the importance of organic anion transporters (OATs) and other active and passive transport molecules in the movements of urate in both directions across the proximal tubule (Figure 94-7).[57,58]

**Urate Resorption.** Urate *resorption* in the proximal tubule depends on the action of several apical surface transporters and at least one resorption transporter at the basolateral surface (see Figure 94-7). In humans, the most important of the apical-surface transporters appears to be URAT1 (gene *SLC22A12*). URAT1 acts as a urate/anion exchanger to transfer urate from the tubule lumen to the epithelial cytosol. The major inorganic counter ion for URAT1 activity is $Cl^-$. However, organic anions such as lactate, pyrazinoate, and nicotinate can substitute for chloride, with potential clinical consequences, as discussed subsequently. The importance of URAT1 to renal urate resorption is indicated by the fact that patients with inactivating mutations of URAT1 excrete nearly 100% of their filtered urate and demonstrate low serum urate levels (along

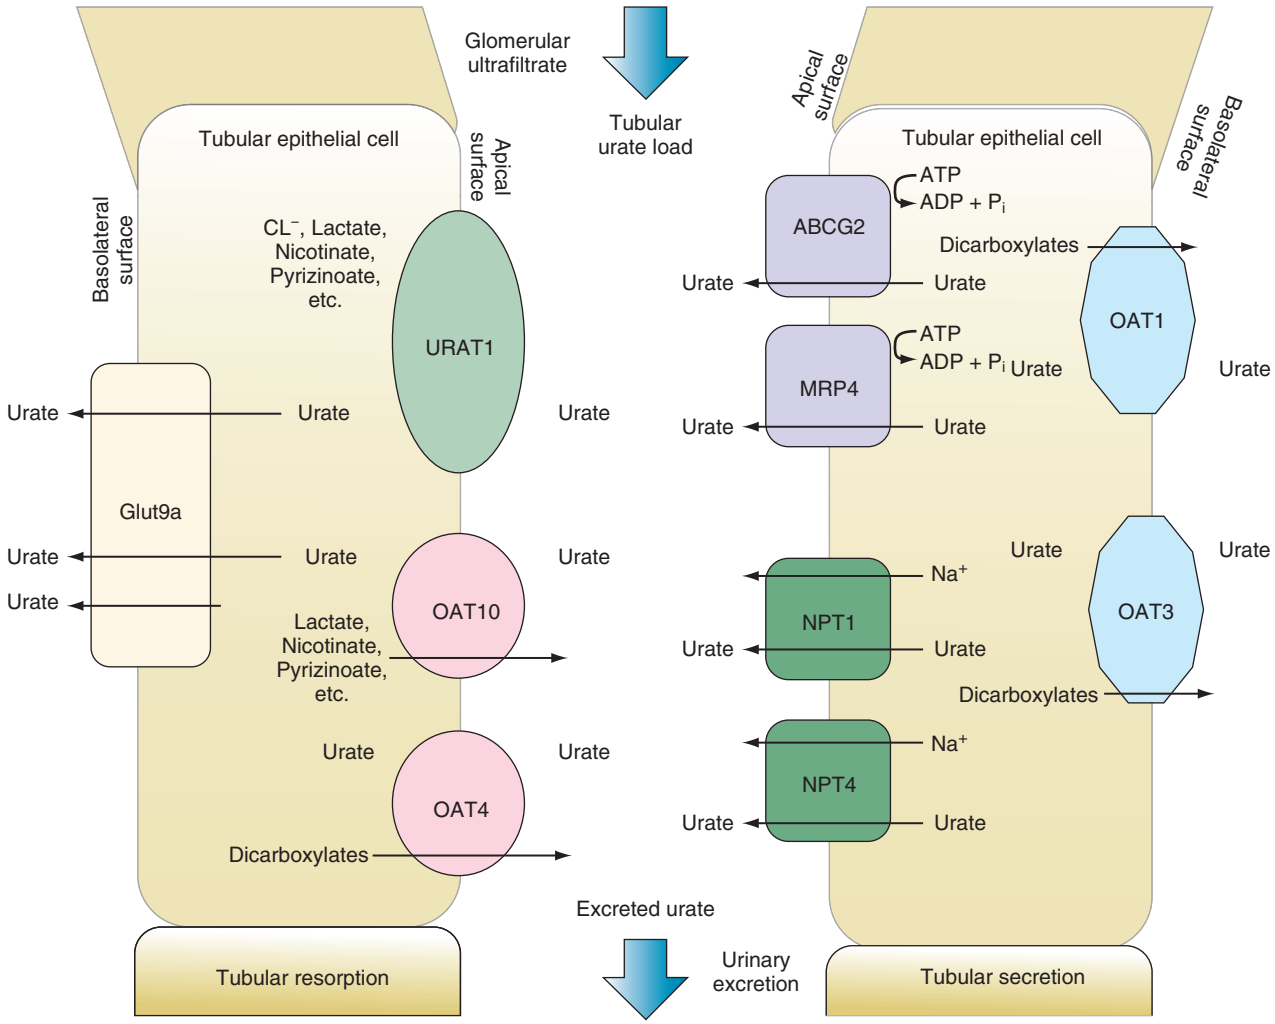

**Figure 94-7** Renal tubular handling of urate. Both urate resorption and urate secretion are handled by the epithelial cells of the proximal tubule. For simplicity, resorption is shown on the *left side* and secretion on the *right side* of the figure. **Resorption:** Multiple apical transporters (URAT1, organic anion transporter [OAT]4, and OAT10) move urate from the proximal tubule ultrafiltrate into the epithelial cytosol. Of these transporters, URAT1 appears to be most important. Both inorganic ($Cl^-$) and organic (e.g., lactate, nicotinate, and pyrazinoate) counter ions promote urate transport at this step; therefore, rises in organic acid levels can promote urate retention and hyperuricemia. Urate is subsequently transported from the cell to the interstitium by the basolateral transporter Glut9a. **Secretion:** The organic anion transporters OAT1 and OAT3 move urate from the interstitium to the epithelial cell interior, using dicarboxylates as counter ions. Urate within the epithelial cell is moved out to the tubular fluid by multiple transporters. Urate secretion by some transporters (ABCG2 and MRP4) is adenosine triphosphate (ATP) dependent, whereas other transporters (NPT1 and NPT4) move urate via cotransport of $Na^+$. Accordingly, sodium depletion can promote hyperuricemia. ADP, Adenosine diphosphate.

with increased urinary uric acid levels and risk for uric acid kidney stones).[59-63] Moreover, several well-established uricosuric drugs including probenecid, benzbromarone, losartan, and high-dose salicylates act primarily by inhibiting URAT1.[64,65] This understanding of URAT1 activity has recently led to the development and approval of lesinurad in the United States, making it the first uricosuric drug specifically designed as a URAT1 inhibitor. Conversely, other mutations in the URAT1 gene appear to convey a risk for increased urate resorption and hyperuricemia, presumably through a gain-of-function effect.

OAT4 (gene *SLC22A11*) and OAT10 (gene *SLC22A8*) are two other apical anion transporters involved in renal uric acid resorption. Like URAT1, OAT10 is an anion exchange transporter; as with URAT1, counter ions that can promote urate transport by OAT10 include lactate, pyrazinoate, and nicotinate. In contrast, although OAT4 also transports urate from the tubular lumen to the cytosol of renal epithelial cells, the counter ions it employs tend to be dicarboxylates.[57,66]

Urate transport by URAT1, OAT4, and OAT10 would lead to accumulation of urate intra-cellularly in renal tubule cells and presumably to gradients that eventually would impair further urate uptake if a mechanism did not exist to transport intra-cellular urate out of the cell at the basolateral surface. This function appears to be served by Glut9a (gene *SLC2A9*, also confusingly known as *URATv1*), which was first identified as a glucose transport family protein but has little or no glucose transport capacity. Instead, Glut9a is an effective transporter of urate from the renal epithelial cell out into the renal interstitium.[67,68] A number of different inactivating mutations of Glut9a have been identified in both humans and mice; in each case the result is impaired urate resorption, increased urate excretion, and hypouricemia.[67,69-74] Glut9a and its splice variant, Glut9b, are also expressed on other cells including chondrocytes, leukocytes, intestinal cells, hepatocytes, and vascular smooth muscle cells; the role of Glut9 proteins (and the impact of probenecid, which inhibits Glut9, as well as URAT1) on these cells is actively being explored.[75-77]

**Urate Secretion.** Other transport proteins in the renal tubule epithelium regulate the *secretion* of urate from the peritubular interstitial fluid into the tubular lumen (see Figure 94-7). At the basolateral surface, OAT1 and OAT3 (genes *SLC22A6* and *SLC22A8*, respectively) transport urate from the interstitium into the epithelial cell cytosol. These transporters act via exchange with dicarboxylate anions and transport not only urate but other organic anions and some drugs.[78] At the apical surface of proximal tubule cells, two proteins have been identified that serve as urate-extruding transporters. The multidrug resistance protein MRP4 (gene *ABCC4*) mediates ATP-dependent urate transport.[79] Whether energy failure promotes hyperuricemia by impairing MRP4 has not been established but would seem plausible. The ABCG2 transporter (gene *ABCG2*) also directly mediates renal urate excretion.[80,81] Genetic association studies have implicated two other anion transport proteins as playing a role in apical urate transport outside of the cell, namely NPT1 (gene *SLC17A1*) and NPT4 (gene *SLC17A3*).[80,82-84] Additionally, genetic studies have implicated nontransporter proteins as playing roles in urate excretion, including PDZK1, CARMIL, NHERF1, SMCT1, SLC5A8, SMCT2, and SLC2A12. It is thought that some of these proteins may contribute to a macromolecular complex regulating urate transport.[85]

## Renal Causes of Hyperuricemia

**KEY POINT**

**Decreased renal excretion of urate because of intrinsic or secondary causes results in elevated levels of serum urate.**

Most patients with hyperuricemia underexcrete urate; that is, for any given serum urate level, their degree of renal urate excretion is inadequate and less than is seen in normal control subjects (Figure 94-8). The mechanisms of urate underexcretion are various and stem from either primary or secondary renal effects.

### Primary Urate Underexcretion

In a subset of patients, hereditary defects of renal tubule urate excretion result in hyperuricemia. With the identification of the aforementioned renal urate transporters, the underlying basis for some of these defects has become apparent. For example, ABCG2 loss of function mutations promote hyperuricemia, and up to 10% of gout cases in white Europeans may be attributable to hyperuricemia induced by defects in the urate exporter ABCG2.[80,81,86] As previously noted, ABCG2 also appears to play an important role in gastrointestinal urate excretion, and ABCG2

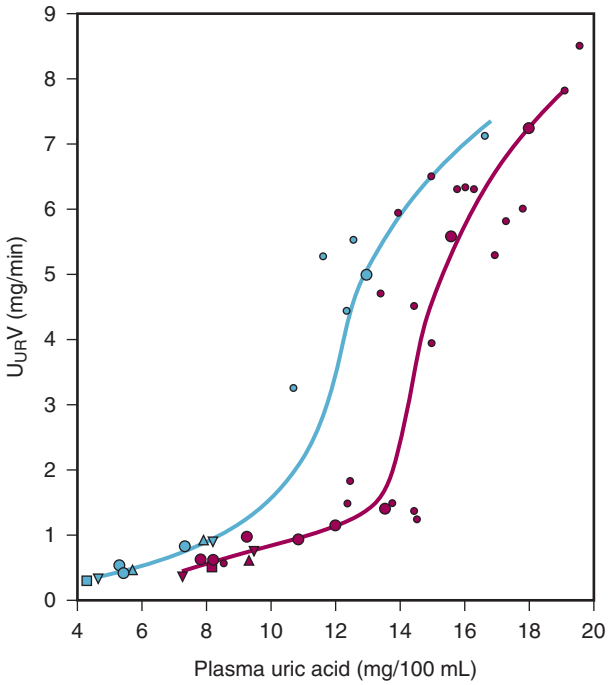

**Figure 94-8** Plasma uric acid versus renal urate excretion in underexcreters versus normal control subjects. The *red line* and *red symbols* represent urate underexcreters; the *blue line* and *blue symbols* represent normal control subjects. For any given plasma urate level, the patients who underexcrete urate demonstrate a lower degree of urinary urate; they thus require higher serum urates to produce urate-comparable urate excretion. (Large and small circles represent mean and representative individual data for the experiment, respectively.) $U_{UR}V$, Urine urate excretion rate. *(From Wyngaarden JB: Gout,* Adv Metabol Dis *2:2, 1965.)*

dysfunction may therefore also contribute to urate retention and hyperuricemia on a gastrointestinal basis.[87,88] Conversely, gain of function mutations in several transport-related proteins (e.g., PDZK1, CARMIL, and NHERF1) may promote hyperuricemia by enhancing URAT1 (i.e., renal urate resorption) activity. Patients with intrinsic tubular defects leading to net urate underexcretion typically display normal renal filtration and normal serum creatinine levels.

Familial juvenile hyperuricemic nephropathy (FJHN), also known as *medullary cystic kidney disease* (MCKD), constitutes a group of autosomal dominant disorders characterized by early hyperuricemia and progressive chronic kidney disease.[89] The hyperuricemia typically precedes the renal insufficiency and is considered to be primary. Three variants are recognized, designated MCKD 1, 2, and 3. In MCKD2, mutations in the uromodulin gene result in underproduction and/or misproduction of uromodulin (Tamm-Horsfall protein), the most prevalent protein secreted by the kidney.[90-92] The probable importance of uromodulin deficiencies to FJHN has recently been underlined by the observation that although patients with the MCDK1 and 3 subtypes of FJHN have mutations that are not in the uromodulin gene, they nevertheless display a phenotype of decreased uromodulin expression.[93] The mechanisms through which uromodulin deficiencies predispose to hyperuricemia are not yet understood, but mice transgenic for human uromodulin mutations experience renal tubular abnormalities and concentrating defects.[94]

### Secondary Causes of Renal Urate Underexcretion

A large number of underlying causes can result in nephrogenic retention of urate and subsequent hyperuricemia**.** These causes include acute or chronic renal failure, the effects of toxins and drugs, and systemic illnesses that alter renal urate handling directly or indirectly.[95]

**Age and Sex.** Classic studies by French and colleagues[96] documented that serum urate levels tend to be low in children. In males, urate levels increase precipitously at puberty, a time when females experience only a slight increase in serum urate. For women, a gradual increase over the subsequent years, followed by another rise at menopause, finally brings the serum urate level near to that of men, consistent with Hippocrates' astute aphorisms that "a young man does not take the gout until [around the time] he indulges in coition" and that "a woman does not take the gout, unless her menses be stopped."[96,97] This discrepancy between men and women, in the period between puberty and menses, suggests strongly that sex hormones play a role in urate regulation. Indeed, studies suggest that in women, both estrogen and progesterone may promote renal urate excretion.[98] Follicle-stimulating hormone has been associated with a slight increase in urate levels, though the mechanism remains unclear.[99] Conversely, an active role for androgens in promoting hyperuricemia may be inferred from Hippocrates' assertion that "Eunuchs do not take the gout" and from studies indicating that androgens and estrogens have opposing effects on renal organic anion transporters.[100] In pregnant women, increases in serum urate levels are characteristic of pre-eclampsia, a reproductive emergency consisting of hypertension and proteinuria. The hyperuricemia of pre-eclampsia is thought to result from that condition's renal dysfunction; hyperuricemia in pre-eclampsia does not lead to gout but is considered by some investigators to secondarily contribute to pre-eclamptic renal dysfunction in a positive feedback loop.[101]

**Systemic Illnesses.** Glomerular insufficiency (i.e., a reduction in the glomerular filtration rate), whether acute or chronic and for whatever reason, promotes urate underexcretion and hyperuricemia (Table 94-1). The mechanisms of hyperuricemia in patients with renal insufficiency are complex but depend first and foremost on decreased delivery of a filtered urate load to the renal tubule. At high levels of azotemia such as are rarely seen in this era of dialysis (blood urea nitrogen >100 mg/dL), hyperuricemia is practically universal. Lesser degrees of renal failure are more variably accompanied by hyperuricemia because decreases in glomerular filtration rate promote some compensatory increase in renal tubule urate secretion, and possibly because of gastrointestinal compensation as well. The effects of renal insufficiency on hyperuricemia may be more apparent in patients who also possess other risk factors for elevated urate levels. An association between congestive heart failure and hyperuricemia has also been reported. Although the direction of causality in this relationship has not been fully established, it is likely that the reduced renal perfusion seen in persons with congestive heart failure can promote urate retention.[102] Because glomerular insufficiency is a condition that accrues among older populations, it likely contributes to the higher rate of hyperuricemia and gout among older adults.[2]

Various forms of organic (metabolic) acidoses may promote renal underexcretion of urate. Thus patients with lactic acidosis (e.g., in hypoxia, sepsis, liver or kidney disease, post-surgery or myocardial infarction, during excessive anaerobic exercise, or in response to certain drugs such as metformin) may become hyperuricemic. Similarly, patients experiencing ketoacidosis (e.g., alcoholic or diabetic ketoacidosis or starvation ketosis) also may experience hyperuricemia. Lactic acidosis may also occur as a result of ketoacidosis. Although the mechanisms of these effects were previously considered to result from direct competition between the organic acids and urate for tubular excretion, they are probably better considered from the perspective of recent discoveries in renal urate transport (previously described). In particular, organic acids serve as exchange anions for the apical surface renal urate transporters URAT1 and OAT10. Such acids therefore provide a motive force for increased urate resorption in the proximal tubule.

Dehydration (volume depletion) on any basis promotes hyperuricemia.[103] Once again, the mechanisms are complex but include decreased renal perfusion and subsequently decreased urate filtration and delivery to the proximal tubule. Subsequent sodium retention will reduce tubular urate secretion, probably at the $Na^+$/urate co-transporters NPT1 and NPT4. Patients exposed to low-sodium diets may also retain urate in an effort to retain sodium.

Several metabolic and/or endocrinologic conditions have been associated with hyperuricemia, although whether these conditions represent independent associations has not been determined. These conditions include hypo- and hyperthyroidism and hypo- and hyperparathyroidism. Obesity is associated with hyperuricemia,[104] and weight loss has been shown to reduce both serum urate levels[105] and risk of gout.[106] Although it appears likely that adiposity itself may promote hyperuricemia, this relationship is complex because adiposity also may reflect diet and thyroid status. Patients who have undergone a renal transplant experience increases in the prevalence of hyperuricemia and gout (2% to 13%). It is likely that the hyperuricemia in patients who have had a renal transplant is not related to the transplant per se but to other factors such as intrinsic renal insufficiency, diuretic use, and especially the use of cyclosporine to suppress rejection (discussed further in a subsequent section).[107] Reciprocally, some studies suggest that hyperuricemia in transplant patients may contribute to worsening renal function.

The interaction between diabetes and hyperuricemia is complex and may be bidirectional (see subsequent section). An association between insulin levels and gout has been recognized, suggesting that insulin may adversely regulate urate levels, possibly through renal mechanisms. Consistent with this possibility, a recent study demonstrated that the initiation of insulin in diabetics resulted in increased serum urate levels.[108] Genetic polymorphisms in the peroxisome *proliferator-activated receptor γ (PPARγ)* gene *(PPARG)*, which are well known to be associated with obesity and metabolic abnormalities, may also be associated with increased risk of hyperuricemia. Patients with genetic polymorphism-associated metabolic abnormalities involving glucose and lipid metabolism (GCKR), cholesterol and diabetes mellitus (MYL2-CUX2), and regulation of glutamate signaling (CNIH-2) have also shown an increased susceptibility to gout.[74] Additional, wider population genome-wide association studies including fine mapping and functional analysis are needed to confirm associations with these genes.

**Medications.** Diuretics are among the most commonly used agents to treat hypertension and congestive heart failure, and it has long been appreciated that many diuretics promote hyperuricemia and subsequent gout (Table 94-2).[109,110] Despite early assessments suggesting otherwise,[111] the increase in gout risk as a result of diuretic use is substantial and may range as high as 3- to 20-fold.[112] The mechanisms through which diuretics raise serum urate are incompletely elucidated but include the induction of sodium wasting and volume depletion, with a resultant decrease in the fractional excretion of urate.[113] However, individual diuretics may also have more specific and direct effects on renal urate handling. For example, loop diuretics such as furosemide and bumetanide interact directly with the tubular urate transporter NPT4,[84] and both thiazide and loop diuretics inhibit the renal urate exporter MRP4.[114] Indeed, despite the volume-depleting effects of diuresis, not all diuretics promote hyperuricemia. For example, the potassium-sparing diuretics triamterene, amiloride, and spironolactone do not increase urate levels. Interestingly, some diuretics actually lower serum urate levels, apparently by directly promoting renal urate excretion even as they induce volume depletion. One such drug was tienilic acid, an effective diuretic and antihyperuricemic that was withdrawn from use as a result of hepatotoxicity.

Several drugs that are weak organic acids may raise serum urate by serving as counter ions to promote urate retention by URAT1 and OAT10. These drugs have also been assumed to inhibit tubular secretion, possibly by acting as urate competitors. Among these agents is the lipid-lowering drug nicotinic acid, which may not only block urate secretion but also promote urate formation.[110] Low-dose salicylates including the low doses of aspirin used for cardioprotection may also raise urate by impairing renal urate efflux.[114] At high doses, salicylates become uricosuric, apparently through the inhibition of URAT1.[115] The antituberculous agent pyrazinamide is the most potent urate-retaining agent known.[110] Pyrazinamide is metabolized to pyrazinoate and subsequently to 5-hydroxypyrazinoate[116]; it is likely that these organic anions act in a manner similar to nicotinate and salicylate. Another antituberculous agent, ethambutol, can also reduce renal tubular urate excretion

and promote hyperuricemia. However, the mechanism of action of ethambutol is not well established.[117] In contrast to calcium channel blockers that modestly promote serum urate excretion, β-blockers are associated with increased serum urate levels, possibly as a result of decreased renal perfusion.[118]

The immunosuppressant cyclosporine is well known to promote decreased renal urate excretion and hyperuricemia. Cyclosporine causes tubulointerstitial injury and arteriolar hyalinosis; reciprocally, hyperuricemia may exacerbate the nephrotoxic effects of cyclosporine.[119,120] Tacrolimus, which has a mechanism of immune action similar to that of cyclosporine and also can impair renal function, does not promote similar levels of hyperuricemia. Moreover, the effect of cyclosporine on urate retention appears to exceed its effects on renal filtration, suggesting a probable direct effect on tubular urate transport and subsequent urate excretion.[110,121,122] Most studies of the effects of cyclosporine on urate have been performed with patients who have undergone a renal transplant; the effects of cyclosporine on urate in other settings are less well established.

**Toxins.** Several toxins can affect the kidney and promote hyperuricemia. Chief among these toxins is lead.[123,124] Lead exposure is common in Western society, but but excessive exposure occurred during some periods (e.g., during the Roman Empire). A connection between lead exposure, hyperuricemia, and gout has been suspected at least since the 18th century. In the 20th century, a large cohort of patients with lead-induced hyperuricemia (saturnine gout) was recognized during and after the era of Prohibition, predominantly in the Southeastern United States and relating to the home brewing of whiskey (moonshine, or white lightning) using lead-lined vessels (typically, automobile radiators). Lead consumption results in lead distribution to a reservoir in bone and may have adverse effects on the CNS as well. In the kidney, lead poisoning leads to interstitial and perivascular fibrosis, as well as glomerular and tubular degeneration.[125,126] Although patients with lead nephropathy initially experience mild to moderate renal insufficiency, their clearance of urate is excessively limited, indicating a tubular defect in urate excretion.[127] Suggestions that lead exposure may also promote purine turnover are provocative but have been less well supported.[128] Although saturnine gout is currently a relatively rare condition, epidemiologic data suggest that it may be more prevalent than is commonly assumed.[129] In patients with moonshine nephropathy (as opposed to chronic lead poisoning from other sources), associated lifestyle factors (e.g., alcohol consumption and obesity) may play a significant role in the genesis of the hyperuricemia.[130]

Patients with chronic beryllium poisoning, usually as a result of an occupational exposure, may also experience diminished renal urate excretion and hyperuricemia.[131]

## Diet and Uric Acid

**KEY POINT**

**Diet can have significant effects on serum urate levels by serving as a source of dietary purines and by altering the metabolic production and/or renal excretion of uric acid.**

A number of dietary components can affect serum urate levels, mainly by leading to urate overproduction. Several other dietary components may have the capacity to lower serum urate levels.

### Purine-Rich Foods

Purine-rich foods are a major source of daily purine load and hence a major source of generated urate. However, not all purine-rich foods convey equivalent risk: seafood and red meat, particularly organ meats, convey an increased risk for hyperuricemia, whereas consumption of purine-rich, leafy-green vegetables apparently does not convey such a risk.[132] Earlier authors emphasized the limited effect of purine intake, with studies suggesting that alterations in purine intake may result in, at most, changes in serum urate of about 1 mg/dL.[95,133] However, such studies have rarely accounted for the role of renal urate excretion in the context of diet. Thus it is worth considering if, for a patient who is intrinsically unable to excrete serum urate, an increased dietary purine load may produce more profound increases in serum urate levels than would be seen in a patient with normal excretory capacities. In contrast to purine ingestion, protein consumption does not increase the risk of hyperuricemia and/or gout, a point of occasional confusion for practitioners, because many high-purine foods are also high in protein.[132]

### Fructose

As early as 1901, Osler[134] recognized the ability of fructose to provoke gout flares. Little attention was given to this observation until the 1960s and 1970s, when it was demonstrated that fructose loads, administered orally or intravenously, cause transient rises in serum urate levels, particularly in persons with gout.[135,136] These effects are reproduced with consumption of sucrose (which contains fructose) but not with consumption of glucose or galactose.[137] Biochemical analysis of fructose metabolism has provided insight into the mechanisms of fructose-induced hyperuricemia, which does not provide purines directly but instead alters metabolism to promote purine and hence urate synthesis (Figure 94-9).

The first step in fructose metabolism is the donation of a phosphate from ATP to form fructose-1-phosphate (enzyme phosphofructokinase), generating ADP. ADP is converted to AMP (enzyme adenylate kinase), which in turn is degraded via several steps to uric acid. In effect, fructose serves as a phosphate "sink" because the donated phosphate is no longer available for the regeneration of ATP from AMP and ADP. Because both $P_i$ and ATP inhibit the purine degradation pathway (through inhibition of AMP deaminase and 5′ nucleotidase, respectively), depletion of these compounds promotes the formation of uric acid as well.[138] Depletion of ADP/AMP also impairs feedback inhibition of PRPP synthase and promotes purine biosynthesis. Epidemiologic studies confirm a role for fructose consumption in hyperuricemia; patients who consume excessive fructose in the form of fructose-sweetened soft drinks or fruit juices demonstrate both higher serum urate levels and an increased incidence of gout.[137,139-145] The probable importance of fructose is underscored by the fact that the rise in the prevalence of gout during the past several

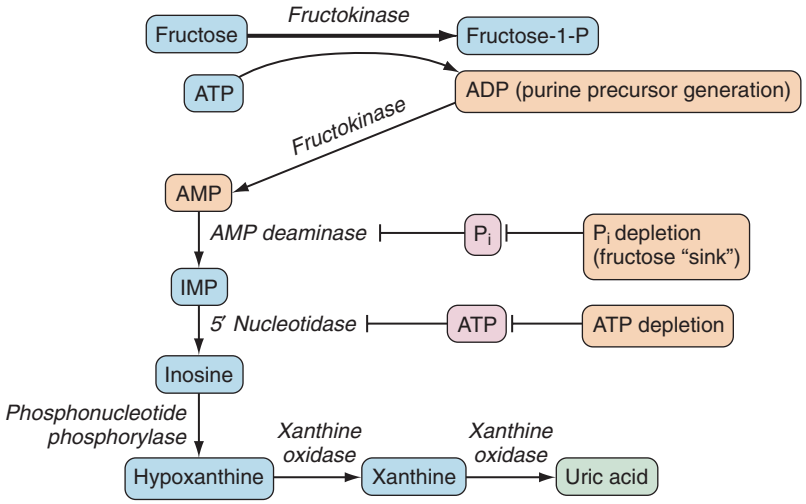

**Figure 94-9** Fructose and the generation of uric acid. Ingested fructose is converted to fructose-1-phosphate, a process that uses adenosine triphosphate (ATP), generates adenosine diphosphate (ADP), and sequesters inorganic phosphate (fructose/phosphate "sink"). The ADP generated then serves as a substrate for urate generation, whereas the depletion of ATP and $P_i$ results in decreased feedback inhibition of the enzymes that mediate uric acid synthesis. AMP, Adenosine monophosphate; IMP, inosine monophosphate.

decades has occurred in parallel with an increased industrial use of fructose, rather than dextrose (glucose), as a major additive in soft drinks and prepared foods.

### Alcoholic Beverages

Ethanol ingestion is associated with the development of gout, and ample physiologic and epidemiologic data confirm that ethanol consumption promotes the development of hyperuricemia.[146-150] Ethanol is a particularly effective agent for raising serum urate levels because it works through multiple mechanisms. Chief among these is the requirement for ATP degradation during ethanol metabolism, resulting in increased purine turnover and urate generation.[151,152] The ability of binge alcohol consumption to induce increases in lactate levels also contributes to hyperuricemia by decreasing renal urate excretion, likely through effects on URAT1, as previously discussed.[153,154] Ethanol consumption also promotes a diuresis, probably via anti-diuretic hormone suppression[155]; dehydration and volume depletion then promote renal urate retention. At acutely high levels of alcohol intake in individuals who chronically consume ethanol ketoacidosis may ensue, particularly in the setting of transient starvation and/or vomiting[156]; in such settings, uric acid secretion may be inhibited, or uric acid resorption may be promoted by 3-hydroxybutyrate and acetoacetate, in much the same manner as lactic acid.[157] As a dietary matter, some alcoholic beverages, particularly beers and ales, are high in purines, mainly in the form of guanosine.[149] Indeed, consumption of ethanol-free beer transiently raises serum urate levels, although not to the extent of beer itself.[158] The importance of purine load in alcoholic beverages may be underlined by the fact that, in contrast to beer, moderate consumption of wine (which is relatively low in purines) does not increase serum urate levels.[150,159] As previously noted, saturnine gout contracted from lead-adulterated moonshine may also contribute to hyperuricemia in the setting of alcohol consumption.[124]

### Other Dietary Components

Recent epidemiologic and physiologic data indicate that consumption of low-fat dairy products is independently associated with reduced serum urate levels and risk of gout.[132] In physiologic studies, consumption of milk or milk proteins has a direct uricosuric effect that results in lowering of serum urate.[160] Interestingly, dairy products may also have anti-inflammatory effects.[161] Regular heavy coffee consumption (4 to 6 cups daily) may have urate-lowering properties that are independent of caffeine[162-164]; these effects appear to be concordant with a reduced risk of incident gout.[165,166] In contrast, intermittent heavy coffee consumption may be transiently prohyperuricemic, perhaps as a result of caffeine-induced diuresis and volume depletion. Increased intake of vitamin C has been epidemiologically associated with decreased serum urate levels, but this effect was not confirmed in a prospective study.[167,168] A limited number of studies support the possibility that consumption of cherries, a long-standing complementary medicine treatment for gout, may produce a uricosuric effect and reduce the risk of gout flares.[169,170]

## CRYSTAL FORMATION: THE TRANSITION FROM HYPERURICEMIA TO GOUT

**KEY POINT**

**Monosodium crystal formation involves physicochemical processes but may be regulated by synovial fluid proteins and immunoglobulins.**

Soluble urate does not induce gouty flares; only crystallized urate promotes acute inflammation. Urate crystallization is therefore a critical step in the progression from hyperuricemia to frank gout.[171,172]

Uric acid is a weak organic acid (pKa1 of 5.75 [position 9] and pKa2 of 10.3 [position 3]). At physiologic pH (7.4), approximately 98% of uric acid exists in the form of monosodium urate (MSU) monohydrate. At concentrations greater than 6.8 mg/dL, MSU exceeds its limit of solubility in serum under physiologic conditions, which is the biochemical definition of hyperuricemia. Exceeding the urate solubility threshold potentiates the precipitation of needle-shaped crystals and results in inflammatory responses. However, Sir William Roberts recognized that not all patients with hyperuricemia experienced gout and drew a distinction between hyperuricemia and the crystallization of MSU.[173] Epidemiologic studies also suggest that urate crystal formation and the consequent development of acute gout may occur in a minority of subjects with hyperuricemia.[174] Therefore factors other than hyperuricemia must influence the formation of urate crystals.

In vitro models have shed light on the relationship between urate crystallization and environmental factors such as pH, temperature, salt content, vibration, and large molecules.[175-177] The fact that urate may more readily precipitate at both lower pH and lower temperature, for example, provides a possible rationale for the fact that gout flares are most commonly seen (50% as an initial presentation and eventually 90% of all gout patients) in the first metatarsophalangeal joint, which is both circumferentially exposed (i.e., relatively low in temperature) and at the farthest outpost of the systemic circulation.

Given that crystal formation and gout flares most commonly occur within the confines of the joint, other investigators have emphasized a possible role for joint biology per se in the formation of MSU crystals. For example, some investigators have suggested that soluble urate is excreted more slowly from the joint than other serum elements, providing a possible mechanism for urate concentration within the joint space.[178] Once urate crystals are formed, the fenestrated endothelium of the synovium might permit the joint space to serve as a crystal "trap," preventing crystals from being dispersed and/or dissolved in the wider circulation. Other investigators have emphasized the possible role of cartilage itself in the precipitation of urate, particularly in the setting of aging and/or osteoarthritis.[179] Potential mechanisms through which aging cartilage might facilitate MSU nucleation/crystallization include changes in the proportions and/or chemical properties of cartilage glycosaminoglycans and proteoglycans, as well as increases in the intra-cellular and extra-cellular lipid content of articular cartilage.[179-181] One recent report suggests that osteoarthritis chondrocytes may actually secrete urate into the joint space, promoting local urate excesses in the synovial fluid.[182]

Several investigators have suggested that urate crystallization may be an immune-assisted process. Kam and colleagues[183] proposed that IgG antibody binding to MSU monomers, which was previously assumed to be nonspecific, may permit the stacking of MSU crystals to occur despite dispersion forces that exist in fluid and tissue. More recently, Kanevets and colleagues[184] postulated a role for urate crystal–specific IgM antibodies in the nucleation and formation of urate crystals.

Although urate precipitation is the *sine qua non* of acute gout, not all urate precipitation may lead directly to acute gouty arthritis. Imaging studies confirm that, in patients with asymptomatic hyperuricemia, urate crystals may nonetheless deposit in both cartilage and synovium.[20,185] These deposits are of consequence not only for their potential to directly damage tissue (see the subsequent section), but also for their role as a reservoir of uncoated and potentially inflammatory urate crystals. Thus local trauma, long recognized as a possible antecedent to acute gouty flares, may physically release cartilage-deposited crystals into the joint space, where they can initiate inflammation. In addition, acute lowering of serum and synovial fluid urate levels (e.g., during initiation of urate-lowering drugs) is well documented to precipitate gouty flares[186] by a mechanism that is most likely akin to that in which glacial melting causes the sloughing off of icebergs and the exposure of previously hidden surfaces. Changes in pH and other physical parameters may have similar effects. These observations have led to a revision of the classical model of gout, wherein urate crystal deposition precedes the first acute flare and acute flares occur as a result of crystal shedding into, rather than direct spontaneous precipitation within, the affected joint(s).[187,188]

## ACUTE GOUT FLARES: THE INFLAMMATORY RESPONSE TO MONOSODIUM URATE CRYSTALS

**KEY POINT**

**Uric acid crystals activate both complement and resident synovial leukocytes, inciting neutrophil influx that itself promotes further inflammation.**

In its crystalline form, uric acid is a potent trigger of inflammation.[189] The phlogistic potential of crystalline urate in human gout was established dramatically in the 1960s by Faires and McCarty,[190] who self-injected urate crystals into their knee joints and experienced flares of acute inflammation. In the clinic, the diagnosis of gout is definitively made upon joint aspiration, with examination of synovial fluid under polarized light microscopy demonstrating the presence of urate crystals, neutrophils, and particularly intra-cellular urate crystals, confirming directed neutrophil phagocytic activity.[191] However, the inflammatory mechanisms of gout are complex and involve not only neutrophils but other cell types, numerous inflammatory mediators, and well-organized sequences of events.[192]

### Uric Acid Crystals and Complement Activation

Complement activation by the alternative pathway is a continuous process in body fluids, in which C3 component activation in the fluid phase is followed by rapid C3b deposition onto nearby surfaces.[193] On most cell surfaces C3 is routinely inactivated by regulatory proteins. In contrast, the polyanionic surfaces of uric acid crystals provide opportunities for unconstrained C3 deposition and subsequent activation of downstream complement components. Weissmann and other investigators[194,195] have demonstrated the ability of urate crystals to activate complement from C2-depleted serum, confirming activation of the alternative pathway. Interestingly, other groups have

confirmed that uric acid crystals also activate complement by the classic pathway (i.e., via C1 activation). Crystal activation of the classic pathway may occur in two ways. First, uric acid crystals may activate the classic pathway by an immunoglobulin-independent, C-reactive protein–dependent pathway.[194,196,197] In addition, it has been shown repeatedly that urate crystals possess the ability to bind antibodies. The specificity of IgG binding, as well as the question of whether antibodies bound to urate crystals can lead to additional activation of the classical pathway, is not fully resolved.[194,197,198] One result of crystal-induced complement cascades is to generate C5a, a potent vasodilator and chemoattractant for inflammatory cells such as neutrophils.[199,200] Urate crystal complement activation may also lead to generation of soluble complement membrane attack complexes, which may activate local cells to promote inflammation.[201] Other proteins of potential import to inflammation, including fibronectin and kininogen, may also adhere to urate crystals.[202]

## Cellular Response to Crystals

### Cell Recognition of Crystalline Urate

MSU crystals interact with, and potently stimulate, a range of inflammatory cells. The manner in which crystals activate cells remains an evolving subject of investigation. Several mechanisms have been proposed, including (1) crystal recognition via toll-like receptors (TLRs), (2) interactions between urate crystals and cholesterol rafts in the cell membrane, and (3) direct phagocytic mechanisms.

TLRs are critical for innate immunity and permit organisms to rapidly recognize bacteria and viruses on the basis of stereotypical features (i.e., pathogen-associated molecular patterns), rather than characteristics unique to the specific invader. Because crystalline urate might theoretically be treated as a foreign molecule, several investigators have examined whether urate crystals activate TLRs. In TLR2 and TLR4 knockout mice, decreased IL-1β and TNF production, as well as decreased neutrophil influx in the urate crystal–induced air pouch inflammation model, argue strongly for a role for TLRs in urate crystal responses.[203] Impairment of urate-driven inflammation in CD14 knockout mice also appears to support a role for TLRs, because CD14 is essential for TLR2- and TLR4-dependent signaling.[204] Interestingly, Joosten and colleagues[205] suggest that TLR2 activation by MSU crystals requires simultaneous exposure of the receptors to C18:0 free fatty acids. However, other researchers observed no effect of multiple TLR knockouts on murine models of urate-induced inflammation.[206] The role of TLRs in urate signaling therefore remains an open question.

Other authors emphasize the ability of MSU crystals to electrostatically interact with cholesterol.[207] Cholesterol-rich regions of plasma membranes (lipid rafts) are characteristically dense in signaling molecules and represent hot spots for cellular activation. Receptor-independent interactions between crystalline MSU and lipid rafts have been demonstrated in dendritic cells, resulting directly in cell activation. The mechanism behind this effect appears to relate to hydrogen bond–dependent aggregation of lipid rafts; aggregation of transmembrane receptors within the rafts then results in activation of immunoreceptor tyrosine-based activation motifs, followed by activation of the signaling molecule Syk.[208,209] Syk activation in turn can induce cell activation, including phosphatidylinositol 3 kinase (PI3K) signaling, cytoskeletal rearrangement, and crystal phagocytosis.

As previously noted, MSU crystals may become coated by immunoglobulins and other serum proteins and may serve as a substrate for complement activation. Thus protein-coated urate crystals may also activate cells via their ability to engage Ig, complement, and possibly other cell surface receptors.[210] Consistent with this model, IgG-coated but not IgM-coated urate crystals have been observed to incite greater inflammatory responses than do those that are not coated.[211]

### Intra-cellular Responses to Urate Crystal Encounters

Activation of cells by urate crystals results in the activation of a number of intra-cellular signaling molecules associated with inflammatory responses. In addition to Syk, these intra-cellular signaling molecules include PI3K; the ERK, JNK, and p38 mitogen-activated protein (MAP) kinases; phospholipases C and D; rho-family proteins; and nuclear factor κB (NF-κB). Depending on the cell type in question, activation of these molecules will result in specific phenotype alterations including cytoskeletal alterations, production of cytokines and lipid mediators, and induction of phagocytosis and superoxide generation.[212-216] Additional responses, secondary to these initial ones, include vasodilation and vascular leakiness, the upregulation of adhesion molecules on endothelial and inflammatory cell surfaces, and cellular chemotaxis, which will be discussed in a subsequent section.

It has long been appreciated that urate crystals can induce macrophages to produce IL-1β and that IL-1β produced in this manner is central to the development of gouty inflammation.[213] However, until recently, the mechanism of urate-induced IL-1β upregulation remained unknown. The NLRP3 (known as NALP3, CIAS1, or cryopyrin) inflammasome is a multimolecular, cytosolic complex with the primary purpose of generating IL-1β, as well as IL-18 and IL-33 (also see Chapter 17).[217] The pro form of IL-1β is cleaved into activated IL-1β by the inflammasome-associated enzyme caspase-1, which may also play a role in IL-1β secretion. In a seminal study, Martinon and colleagues[218] documented the ability of MSU crystals to activate the NLRP3 inflammasome and stimulate IL-1β generation (Figure 94-10). Subsequent inflammatory responses (e.g., TNF production) appear to occur as a result of autoengagement of cell surface IL-1β receptors. The importance of the inflammasome in crystal inflammation has been well documented in mouse models: macrophages from mice lacking inflammasome components generate diminished levels of IL-1β on MSU crystal exposure, and intraperitoneal injection of urate crystals into inflammasome-deficient mice, as well as mice deficient in IL-1β receptors, leads to significantly decreased neutrophil recruitment.[218] Moreover, the ability of IL-1β–directed therapies to abrogate both human gout and murine crystal-induced inflammation speaks to the centrality of IL-1β in the inflammatory response to urate crystals.[219-221]

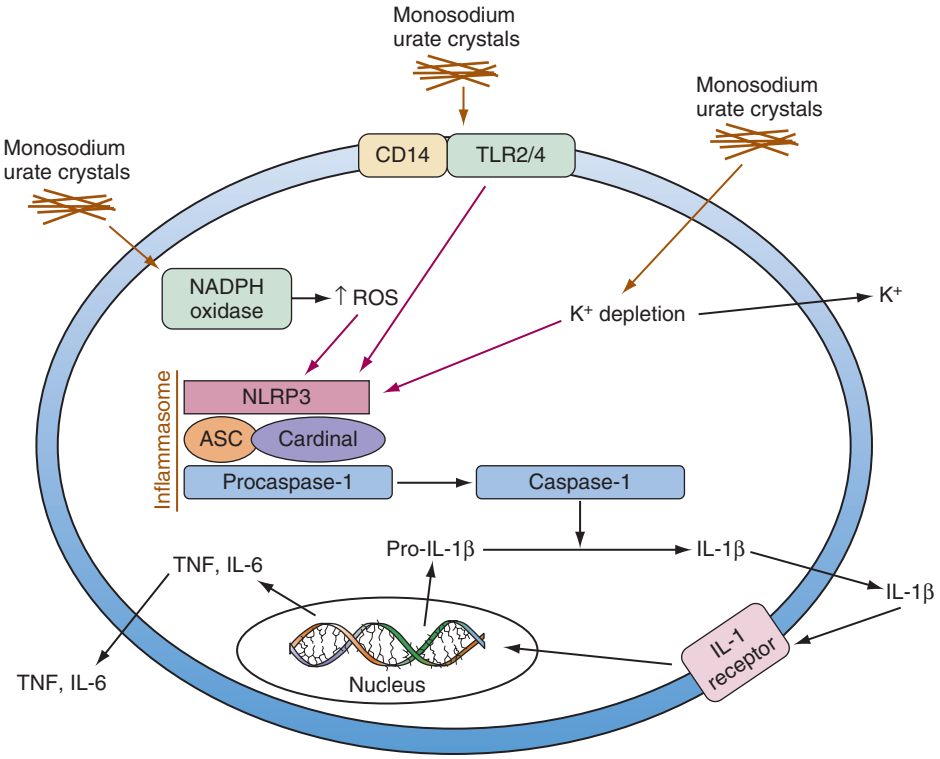

**Figure 94-10** Activation of the NOD-like receptor family, pyrin domain containing 3 (NLRP3) inflammasome by monosodium urate crystals. Activation of the inflammasome by urate crystals results in activation of caspase-1, which cleaves and activates IL-1β and promotes IL-1β secretion. In turn, IL-1β can engage its receptors to secondarily promote the synthesis and secretion of other cytokines such as TNF and IL-6. Three possible mechanisms of inflammasome activation by urate crystals are illustrated: (1) production of reactive oxygen species (ROS), (2) activation of toll-like receptors 2 and 4 (TLR2/4), and (3) potassium depletion, which may be sensed by the inflammasome. The precise roles of these and other mechanisms of inflammasome activation by urate crystals remain a matter of investigation. ASC, Apoptosis-associated speck-like protein containing a caspase-recruitment domain; NADPH, nicotinamide adenine dinucleotide phosphate.

To date, no definitive explanation has been provided with regard to how urate crystals activate the NLRP3 inflammasome. Leading theories center on the inflammasome as an internal sensor for cellular distress resulting from either (1) oxidative stress or shifts in ion concentration or (2) disruption of phagolysosomes.[222,223] In one proposed model, crystal-induced damage to the plasma membrane promotes cellular potassium efflux, and the resultant hypokalemic state activates the inflammasome directly.[224,225] Additionally, crystal activation of the phagocyte NADPH oxidase leads to the generation of reactive oxygen species (ROS), which may then be directly or indirectly sensed by the inflammasome. The ability of large urate crystals to provoke incomplete or frustrated phagocytosis—in which a phagocyte surrounds but cannot fully engulf a target—may lead to an activated state (including oxidase activation) that also contributes to inflammasome activation.[222] The second proposed mechanism of inflammasome activation by MSU crystals is based on the ability of phagocytosed urate crystals to rupture the membranes of phagolysosomes, either by mechanical or physicochemical effects.[226] In this model, phagolysosome rupture leads to cytosolic acidification and intra-cellular release of cathepsin B, each of which has been proposed as a NLRP3 inflammasome activator.[223] These various mechanisms may not be mutually exclusive and may act synergistically (e.g., lysosomal disintegration and cathepsin-B release may themselves promote the production of ROS).

## Initiation and Propagation of the Acute Gouty Flare

The clinical picture of acute gout is one of rapid, almost explosive development of an inflammatory response. Accordingly, cellular changes during the acute flare must reflect the accelerating nature of the inflammation. Beginning with the appearance/release of urate crystals, the initial phase of gouty inflammation must depend on already available local mediators, as well as cells that are both (1) capable of urate crystal responses and (2) already in place within the joint. Clearly, Ig binding and the activation of complement on the crystal surface must be one such early response. Interaction of the crystal with local tissue cells, facilitated in part by IgG and complement opsonization, is also likely to play an early role. Best studied among the early cell type responses is that of the synovial macrophage, a resident cell in the synovial membrane. As previously noted, macrophage activation in response to crystals results in synthesis and secretion of important cytokines such as IL-1β, TNF, IL-6, and the chemokine IL-8 (CXCL8), as well as release of potentially tissue-destroying matrix metalloproteinases (MMPs) and toxic oxygen radicals.[212,213,227,228] Activation of synovial macrophages is contemporaneous with their phagocytosis of urate crystals. Human synovial fibroblasts are also capable of responding to urate crystals, leading to the generation of both inflammatory mediators and metalloproteinases.[227,229] Finally, mast cells are also resident within the synovium and appear to be important in the early phases of

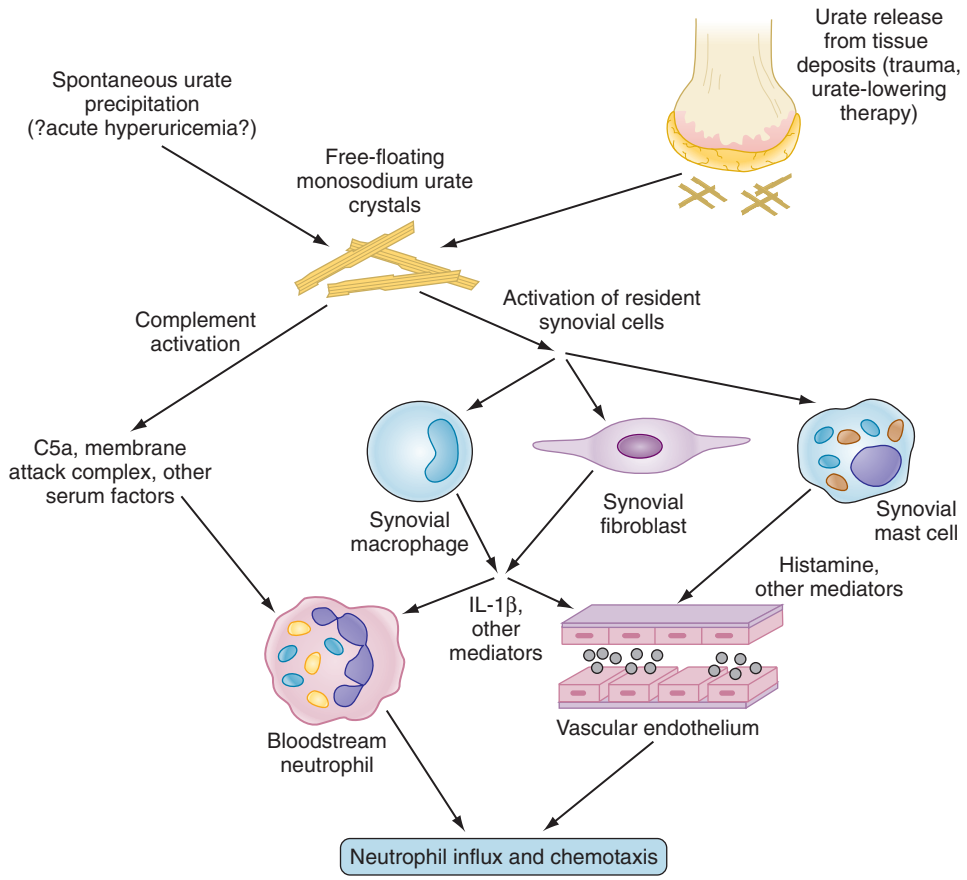

**Figure 94-11** Initial phases of urate crystal–induced activation. The presence of "fresh" urate crystals, resulting either from spontaneous precipitation or the liberation of crystals from established pools, results in direct complement activation and activation of resident cells in the synovium including macrophages, fibroblasts, and mast cells. Activated cells produce IL-1β and other cytokines, as well as multiple other mediators (not all illustrated) that in turn activate both bloodstream neutrophils and endothelial cells. These responses permit neutrophils to adhere to and traverse the endothelium, resulting in neutrophil influx and the further propagation of inflammation as neutrophils undergo direct activation by urate crystals (not illustrated). See text for additional details.

acute gouty responses, as their depletion diminishes inflammation in murine models of crystal-induced inflammation.[230] Mast cells increase in number and activity in the lining of experimental air pouches after MSU crystal injection, suggesting that additional mast cells may be secondarily attracted to the inflammatory site (Figure 94-11).[231]

These early events promote the influx of bloodstream polymorphonuclear neutrophils, the predominant cell in the inflamed gouty joint. Cytokines and other inflammatory mediators produced in the early phase of the crystal response act on the vascular endothelium to promote vasodilation and leakiness and to upregulate the expression of adhesion molecules such as selectins and intercellular adhesion molecules on the vascular surface of endothelial cell.[232] These same cytokines also promote neutrophil activation within the bloodstream, particularly the activation of the integrin adhesion molecule CD11b/CD18. A role for the crystal-generated complement component C5a in the activation of bloodstream neutrophils is also likely because C5a can potently stimulate CD11b/CD18 activation and neutrophil adhesiveness.[233] The result is that neutrophils first adhere tightly to the endothelium and then exit the vasculature, followed by chemotaxis up the C5a complement gradient, leading to encounter with, and phagocytosis of, the provoking urate crystals. The mechanisms of neutrophil activation by crystals include those previously discussed and, importantly, appear to include interactions with CD11b/CD18 (which is also a complement receptor) and the IgG receptor FcγRIIIB. Subsequent neutrophil intra-cellular signaling events include phosphorylation and/or activation of a number of tyrosine kinases including Lyn, Syk, Tec, and Src; activation of PI3K; and activation of phospholipase C.[234] Activation of MAP kinases is probably also involved because these kinases regulate neutrophil adhesion and superoxide generation.[233]

Neutrophils encountering urate crystals can rapidly promote additional inflammation and additional neutrophil influx via several mechanisms (Figure 94-12). First, neutrophils stimulated by urate crystals generate a number of inflammatory mediators and potent neutrophil chemoattractants including IL-1β, IL-8, leukotriene $B_4$ ($LTB_4$), S100A8/A9 (also known as myeloid-related proteins 8 and 14), prostaglandin $E_2$, and crystal-induced chemotactic factor.[234,235] Of these, IL-8 and $LTB_4$ are potent chemoattractants. They play a particularly important role in amplifying the chemoattractant gradient and promoting additional neutrophil influx. Second, neutrophils stimulated by crystals release a wide range of products capable of directly

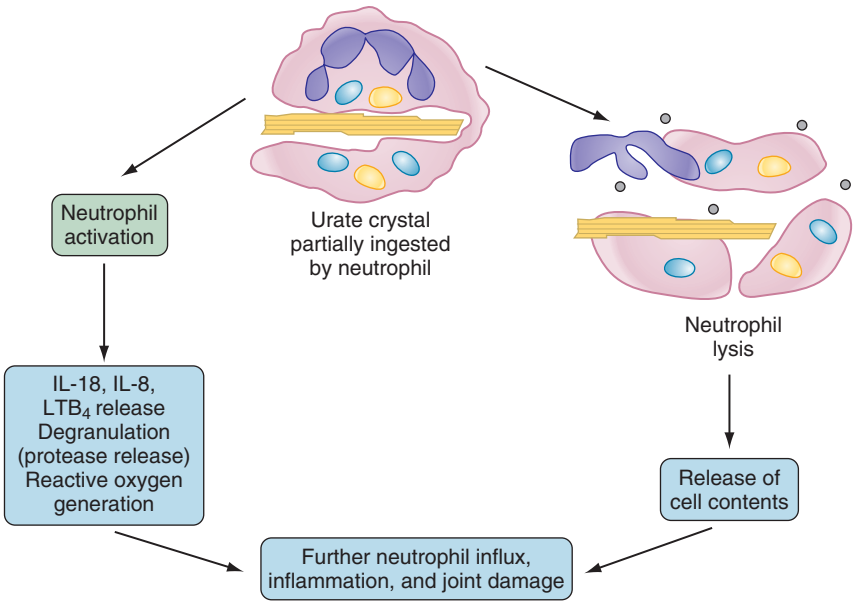

**Figure 94-12** Propagation of the acute gouty response by activated neutrophils. Neutrophils that enter the joint migrate toward and phagocytose crystals. In the case of crystals coated with Igs and complement, the resultant activation results in synthesis and/or release of inflammatory mediators such as IL-1β, IL-8, and TNF, as well as proteases and reactive oxygen species. In the case of uncoated crystals, the crystal frequently interacts with and lyses the membrane of the phagolysosome, spilling toxic contents and leading to cell lysis. In both cases, the result is local tissue damage and recruitment of additional neutrophils from the bloodstream in an explosive inflammatory cycle. $LTB_4$, Leukotriene $B_4$.

damaging local tissues, including oxygen radicals and MMPs such as MMP-8. Although these mediators are intended for digestion of foreign particles within phagolysosomes, the large size of many urate crystals results in incomplete ("frustrated") phagocytosis of the crystals, with the result that lysosomal contents are released into an unsealed phagolysosome and can escape to promote extra-cellular tissue damage ("regurgitation during feeding"). This process appears to be facilitated by crystals coated with Igs.[211] Alternatively, when uncoated crystals are phagocytosed by neutrophils, their ability to interact with the cholesterol-rich bilayers of the phagolysosome results in phagolysosome rupture, cellular necrosis, and direct release of toxic neutrophil contents.[226] In either case, the result is the potential for tissue damage and rapidly accelerating inflammation.

## Resolution of the Acute Gouty Flare

One of the more interesting features of acute gout is that, particularly in the early stages of the disease, most flares are self-limited.[236] Multiple effects have been invoked to explain this phenomenon. Urate crystals may become coated with synovial fluid proteins (e.g., apolipoproteins B and E), thus inhibiting their ability to provoke inflammation.[237] The stress of the gouty flare may promote adrenocorticotropic hormone (ACTH) secretion; in addition to its ability to induce glucocorticoid release, ACTH can bind directly to melanocyte-stimulating hormone receptors to provoke anti-inflammatory effects.[238-240]

Other investigations have emphasized the local, active events through which inflammation may be resolved. For example, in vivo studies using the urate crystal–induced mouse air pouch model of inflammation suggest that local upregulation of expression of $PGD_2$ and 15d-$PGJ_2$ (a spontaneous dehydration product of $PGD_2$) contributes to the resolution of crystal-mediated inflammation, probably through the ability of these molecules to activate the PPARγ.[241,242] Urate crystals also directly stimulate the expression of PPARγ, setting the stage for enhanced suppression of inflammation.[242] 15d-$PGJ_2$ inhibits secretion of IL-1β, IL-6, and IL-12, as well as TNF from macrophages, and downregulates the expression of inducible nitric oxide synthase. Other targets of 15d-$PJG_2$ include PGD receptors and the NF-κB pathway. 15d-$PGJ_2$ also inhibits CXC chemokine production, alters cellular adhesion molecules, and stimulates apoptosis of endothelial cells.[243] Other anti-inflammatory molecules (e.g., IL-10) are also upregulated, and the more recently identified and potent anti-inflammatory resolvins and lipoxins are almost certainly involved.[244]

With regard to the resolution of acute gouty inflammation, it is important to recognize the biologic programs that delay the production of anti-inflammatory molecules until the appropriate phase in the sequence. For example, $PGD_2$ and 15d-$PGJ_2$ production initially decline upon exposure to urate crystals, apparently facilitating the inflammatory response, but then they rebound to act during the resolution phase.[242] Similarly, the generation of anti-inflammatory lipoxins requires the accumulation of at least two active cell types (either neutrophils and activated endothelium or neutrophils and activated platelets), an evolutionary adaptation that creates an intrinsic delay before the anti-inflammatory effects are initiated, and one that may be critical to the rapid resolution of infections.[245]

Consistent with a "time-delayed" process of gout flare resolution, other studies emphasize the roles of the influxing leukocytes themselves in the resolution of the gouty flare. Several studies support the ability of influxing monocyte/macrophages to clear both urate crystals and apoptotic neutrophils that have ingested crystals, resulting in decreased crystal burden.[246,247] Moreover, these influxing macrophages

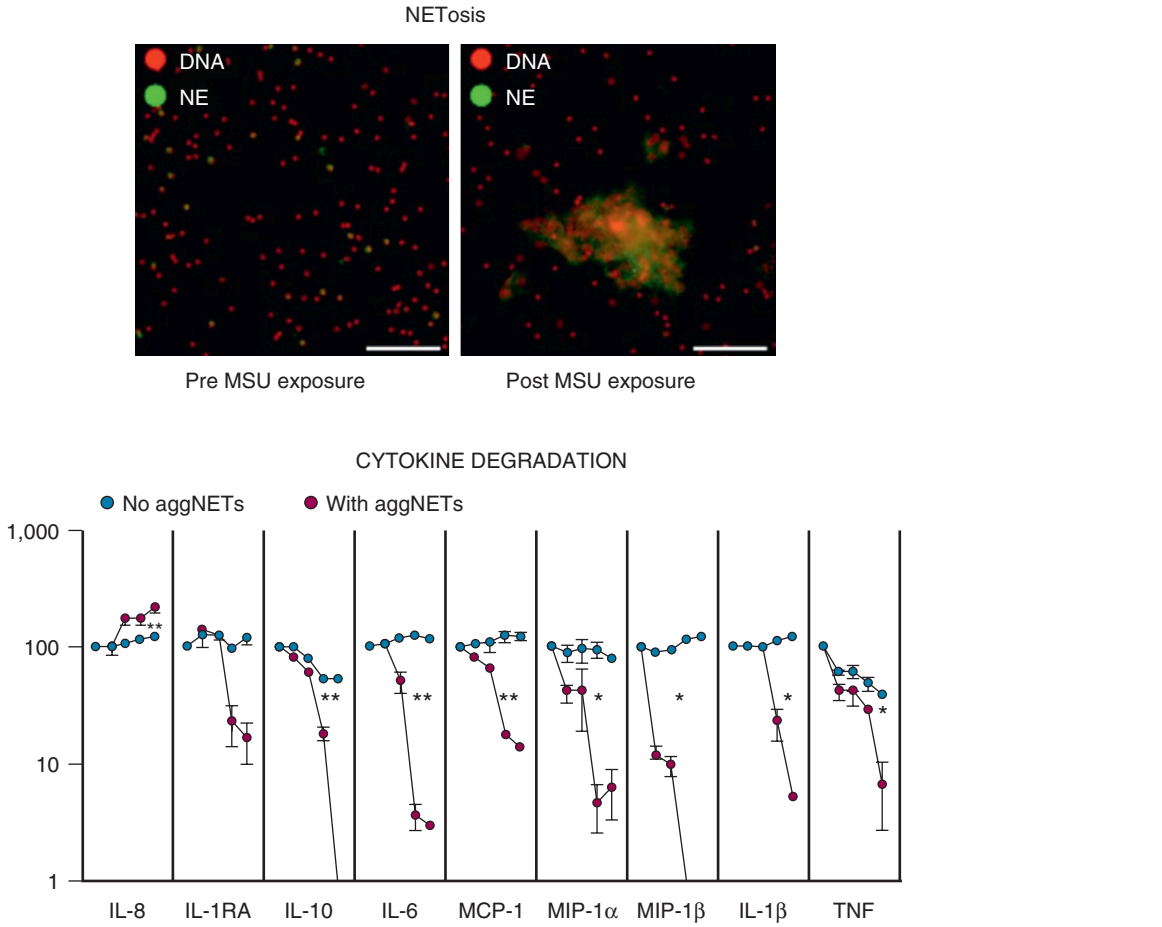

**Figure 94-13** Neutrophil extra-cellular trap (NET)osis and the resolution of acute gout. *Left,* Images of neutrophils before and after exposure to monosodium urate (MSU) crystals, showing the release of an amorphous aggregate of co-localized DNA and neutrophil elastase (NE) in response to urate. *Right,* NETosis and the stable extra-cellular expression of NE permits the rapid degradation of inflammatory cytokines, contributing to resolution of inflammation. MCP-1, Monocyte chemotactic protein-1; MIP-1α, macrophage inflammatory protein-1α. *(Modified from Schauer C, Janko C, Munoz LE, et al: Aggregated neutrophil extra-cellular traps limit inflammation by degrading cytokines and chemokines.* Nat Med *20:511–517, 2014.)*

appear to differentiate into an anti-inflammatory, M2 phenotype (in contrast to the inflammatory M1 phenotype of resident macrophages) and, upon phagocytosing crystals, to release transforming growth factor-β to provoke an anti-inflammatory effect.[248] Similarly, recent evidence suggests that neutrophils that have phagocytosed crystals may release neutrophil extra-cellular traps (NETs), a network of extracellular chromatin that may initially play a pro-inflammatory role in the gouty flare.[249] Subsequently, however, these NETs provide a stable scaffold on which extravasated neutrophil enzymes, particularly neutrophil elastase, encounter and degrade cytokines to promote inflammatory resolution (Figure 94-13).[250]

## Chronic Gouty Arthritis and Tophaceous Gout

The natural history of untreated gout may include eventual progression to a state characterized by chronic inflammation and/or the establishment of macroscopic urate deposits known as *tophi*. Even during the asymptomatic, intercritical periods of gout, low-grade chronic inflammation can persist, with continuous phagocytosis of crystals by leukocytes.[251] In patients with longstanding gout, intercritical inflammation can become frankly apparent and the cytokines, chemokines, proteases, and oxidants that participate in acute inflammation can contribute to chronic synovitis, cartilage loss, and bone erosion, signaling the progression to chronic gouty arthritis (Video 94-1).[252]

Although tophi are composed first and foremost of MSU crystals, they are complex structures in which urate (1) is embedded in a matrix of lipids, proteins, and mucopolysaccharides and (2) drives a persistent inflammatory state.[180] Alternatively, a tophus can be conceived of as a granuloma of mononucleated and multinucleated macrophages arranged in three distinguishable zones (Figure 94-14).[253] MSU crystals and debris constitute the central zone. Surrounding the central zone is the corona zone, consisting of macrophages, multinucleated macrophage-like cells, plasma cells, and mast cells. This biologically active corona is thought to account for the ultrasonographic finding of an anechoic rim that circumscribes a tophus.[254] Eventually, the corona and central zones may become encased by a connective tissue layer, the fibrovascular zone. Within this zone, macrophages express surface markers of recent migration, maturation, apoptosis, continuous recruitment, and pro-inflammatory activation.[255] T and B cells are scattered throughout both outer zones.[253,256] Although classically a late feature of gout, tophi may occur early in the disease,

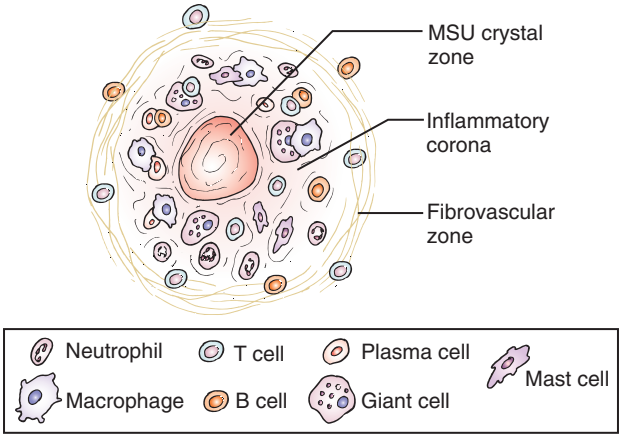

**Figure 94-14** Structure of a tophus. Note the central monosodium urate (MSU) crystal zone, the intermediate corona zone, and the outer fibrovascular zone. *(Modified from Chhana A, Dalbeth N: The gouty tophus: a review.* Curr Rheumatol Rep *17:19, 2015.)*

particularly in patients with renal insufficiency and high serum urates.[257] In some patients, tophi may develop even in the absence of any acute flares.

Tophi are important not only for their role as reservoirs of crystalline urate but also for their ability to damage the tissues in which they reside, including bone, cartilage, and tendons and other soft tissue structures[258] (see Chapter 95). Mechanical factors, induction of lytic enzymes, and synthesis of pro-inflammatory cytokines all contribute to the ability of the tophus to promote erosion and joint destruction.[179] Tophus macrophages produce IL-1β, TNF, IL-6, IL-17, MMP-2, MMP-9, and macrophage CSF (M-CSF).[255] These molecules promote further inflammation and tissue damage, as well as the maturation and activation of osteoclasts that actively resorb bone. For example, M-CSF interacts with M-CSF receptors on osteoclast progenitor cells to promote osteoclastogenesis. Tophus expression of IL-1β and other cytokines has also been shown to inhibit the viability and bone-maintaining effects of osteoblasts.[252,259] Tophus T cells promote bone erosions through the elucidation of receptor activator of NF-κB (RANK) ligand, the major promoter of osteoclastogenesis and osteoclast activation.[260] Additionally, MSU crystals on the cartilage surface drive reduced chondrocyte viability, increased chondrocyte production of degenerative enzymes, and cartilage damage.[261] Even in clinically asymptomatic patients, these inflammatory and erosive processes persist; damage may not be apparent until late in the process.

## EFFECTS OF HYPERURICEMIA IN THE ABSENCE OF GOUT

**KEY POINT**

**Even in the absence of gout, hyperuricemia and soluble serum urate are biologically active and may have previously unappreciated clinical effects.**

In addition to its roles in acute and chronic gouty arthritis, hyperuricemia may have other effects, both adverse and beneficial. Soluble urate is biologically active, with effects on renal and vascular function. Among its mechanisms of action, soluble urate inhibits synthesis of the potent vasodilator nitric oxide; induces smooth muscle cell proliferation by activating MAP kinases; and stimulates cyclooxygenase-2 and platelet-derived growth factor synthesis, all contributing to arterial vasoconstriction.[262,263] Soluble urate has also been shown to directly stimulate the renin-angiotensin system in the kidney and to induce renal interstitial and tubular inflammation.[264,265] As noted in the Evolutionary Considerations section at the beginning of this chapter, these effects may promote hypertension. Other studies suggest that hyperuricemia may also contribute to the risk for cardiovascular disease, although additional research is necessary to better assess the direction of causality.[266] Several recent clinical trials suggest that lowering serum urate levels may reduce the risk of myocardial infarction and slow the progression of renal failure.[267,268] Hyperuricemia may also promote insulin resistance in adipose cells[269-271] and drive gluconeogenesis in hepatocytes,[272] and it has been associated with reductions in $1,25(OH)_2$ vitamin D3 synthesis.[273,274] Urate may also play a role and/or serve as a biomarker in osteoarthritis.[182,275,276] In contrast to the adverse effects of serum urate, accumulating evidence suggests that hyperuricemia may protect against neurologic diseases such as dementia, multiple sclerosis, and Parkinson's and Huntington's diseases.[277-283] Recognition of the biologic complexity of uric acid will lead to a better understanding of its impact on the immune, cardiovascular, endocrine, neurologic, and musculoskeletal systems and to an improved ability to treat hyperuricemia and gout.

CHAPTER 95

# Clinical Features and Treatment of Gout

Christopher M. Burns • Robert L. Wortmann

**KEY POINTS**

- Hyperuricemia is defined as a serum urate level greater than 6.8 mg/dL.
- Acute gout can be treated with NSAIDs, colchicine, corticosteroids, adrenocorticotropic hormone, or IL-1 inhibitors.
- Canakinumab, an anti–IL-1β antibody, has been approved in the European Union for use in patients with acute gout under certain conditions.
- The effectiveness of treatment depends more on how quickly the therapy is initiated than on which agent is used.
- Before initiating therapy with a urate-lowering agent, the patient should be treated with low-dose colchicine or an NSAID to provide prophylaxis against further attacks.
- Regardless of whether a xanthine oxidase inhibitor (allopurinol or febuxostat) or a uricosuric agent (probenecid or benzbromarone) is used to treat hyperuricemia, the patient should receive the lowest dose that maintains the serum urate level below 6.8 mg/dL—preferably below 6 mg/dL.
- The uricase pegloticase should be taken at regular intervals, usually every 2 weeks, and therapy should be stopped when the serum urate level rises above 6 mg/dL, indicating the presence of antidrug antibodies and high risk of an infusion reaction.
- People who are hyperuricemic should be screened for commonly associated comorbid conditions, including hypertension, coronary artery disease, diabetes, obesity, and alcoholism.
- Using a specific urate-lowering agent to manage asymptomatic hyperuricemia is not recommended.
- Hyperuricemic people should try to maintain an ideal body weight, limit alcohol consumption (especially beer), and avoid sweeteners that contain fructose.
- The 2012 American College of Rheumatology Guidelines for Management of Gout has helped clarify treatment strategies.

Gout has been called the "king of diseases" and the "disease of kings." Today, the term *gout* is used to represent a heterogeneous group of diseases found exclusively in humans that include the following characteristics:

- Elevated serum urate concentration (hyperuricemia)
- Recurrent attacks of acute arthritis in which monosodium urate monohydrate crystals are demonstrable in synovial fluid leukocytes
- Aggregates of sodium urate monohydrate crystals (tophi) deposited chiefly in and around joints, which sometimes lead to deformity and crippling
- Renal disease involving glomerular, tubular, and interstitial tissues and blood vessels
- Uric acid nephrolithiasis

These manifestations can occur in various combinations.[1,2]

*Hyperuricemia* denotes an elevated level of urate in the blood. This phenomenon occurs in an absolute (or physiochemical) sense when the serum urate concentration exceeds the limit of solubility of monosodium urate in the serum, which is 6.8 mg/dL at 37°C. Thus a value greater than 6.8 mg/dL indicates supersaturation of body fluids and should be considered unhealthy. A serum urate value in excess of 7 mg/dL begins to carry an increased risk of gouty arthritis or renal stones. Unfortunately, many laboratories report normal levels of serum urate as high as 8.5 mg/dL. These values are derived from population statistics using the mean ± two standard deviations. More than 20% of the U.S. population is hyperuricemic. Therefore sampling a general population gives high "normal" values, resulting in confusion if the clinician does not consider the physiochemical (and therefore more clinically relevant) basis for defining normal.

## EPIDEMIOLOGY

**KEY POINTS**

- Hyperuricemia is common and is directly associated with serum creatinine, body mass index, age, blood pressure, and alcohol intake.
- Serum urate levels are low in childhood and increase in men at puberty and in women at menopause.
- The prevalence of gout ranges from 1% to 15% with a clear increase in incidence in recent years, perhaps related to the adoption of a Western diet and the epidemic of obesity.

Hyperuricemia is fairly common, with prevalence ranging between 2.6% and 47.2% in various populations.[3,4] A variety of factors appear to be associated with high serum urate concentrations. In adults, serum urate levels correlate strongly with serum creatinine and urea nitrogen levels, body weight, height, age, blood pressure, and alcohol intake.[5] In epidemiologic studies, body bulk (as estimated by body weight, surface area, or body mass index) has proven to be one of the most important predictors of hyperuricemia

in people of many different races and cultures, with rare exceptions.[6-8]

Serum urate concentrations vary with age and sex. Children normally have a concentration in the range of 3 to 4 mg/dL because of high renal uric acid clearance.[9] At puberty, serum urate concentrations increase by 1 to 2 mg/dL in males, and this higher level is generally sustained throughout life. In contrast, females exhibit little change in the serum urate concentration until menopause, when concentrations increase and approach those seen in adult men. The mechanism of lower serum urate levels in women is a consequence of sex hormones and is related to a higher fractional excretion of urate as a result of lower tubular urate postsecretory reabsorption.[10]

The incidence of gout varies among populations, with an overall prevalence ranging from less than 1% to 15.3%.[5] This upper limit appears to be increasing.[11,12] The prevalence increases substantially with age and with increasing serum urate concentration. The annual incidence rate of gout is 4.9% for urate levels greater than 9 mg/dL, 0.5% for values between 7 and 8.9 mg/dL, and 0.1% for values less than 7 mg/dL.[13] For serum urate values greater than 9 mg/dL, the cumulative incidence of gout reaches 22% after 5 years.

## ENVIRONMENTAL FACTORS

**KEY POINTS**

**Certain foods promote hyperuricemia and gout, including alcohol, seafood, and red meat.**

**The consumption of some foods, especially milk and yogurt, might be protective.**

An association between alcohol consumption and gout has been recognized for centuries. The risk of developing gout varies by the type of alcohol ingested.[14] Beer, which is rich in purine, carries the highest risk, which is substantially greater than that for liquor. Drinking moderate amounts of wine does not increase the risk of gout. The total quantity of alcohol consumed also strongly correlates with gout. Compared with men who did not drink any alcohol, the relative risk of gout was 1.32 for an alcohol intake of 10 to 14.9 g/day, 1.49 for 15 to 29.9 g/day, 1.96 for 30 to 49.9 g/day, and 2.53 for 50 g/day and higher, with calculations based on 12.8 g of alcohol per 12 oz serving of regular beer, 11.3 g per 12 oz serving of light beer, 11 g per 4 oz serving of wine, and 14 g per shot of liquor.

Diet also influences hyperuricemia and gout. Serum urate levels increase with meat or seafood intake and decrease with dairy intake.[15] Men in the highest quintile of seafood consumption have a 51% higher risk of developing gout, and those in the highest quintile of meat intake have a 41% higher risk. However, consumption of oatmeal and purine-rich vegetables (e.g., peas, mushrooms, lentils, spinach, and cauliflower) is not associated with an increased risk of gout. The consumption of milk one or more times a day or yogurt at least once every other day is associated with lower serum urate levels. Sweeteners containing fructose also contribute to hyperuricemia. The first step in fructose metabolism is phosphorylation by adenosine triphosphate (ATP), which triggers both an increase in purine catabolism and de novo purine synthesis.[16]

## GENETICS

**KEY POINTS**

**Rare forms of early hyperuricemia and gout have a clear genetic and metabolic basis.**

**Gout often runs in families, probably because of inherited factors affecting serum urate levels through renal urate clearance.**

**Recent genome-wide association studies have identified polymorphisms in several candidate genes that encode urate transporters in the renal proximal tubules as determinants of serum urate levels and the risk of gout.**

Since antiquity, gout has been recognized as a familial disorder. The familial incidences reported range from 11% to 80%.[17] These wide discrepancies may be attributed in part to variations in diligence and pursuit of genealogic data. In two large series, one English and one American, about 40% of subjects with gout gave a positive family history of gout. Consideration of all available data suggests that serum urate concentrations are controlled by polygenic traits. Several rare forms of hyperuricemia and gout, such as hypoxanthine phosphoribosyltransferase deficiency, phosphoribosyl-1-pyrophosphate synthetase overactivity, and familial hyperuricemia nephropathy, have a clear genetic basis, with most presenting in childhood or early adulthood.[18] However, in the vast majority of patients with gout, these discrete inborn errors of metabolism are not present and do not explain their disease. In most patients with gout, the mechanism of hyperuricemia is simply inefficient renal excretion of uric acid.[19,20] It stands to reason, then, that some of the familial predisposition to gout is related to inherited variations in renal urate handling. With the recent advances in our understanding of the transport of uric acid in the renal proximal tubule, some of this variability is being clarified. Through genome-wide association studies (GWAS), variations of the *SLC2A9*/*GLUT9* and *ABCG2* genes have been identified as important determinants of serum urate levels (see Chapter 94).[21] Curiously, the data for the role of polymorphisms in URAT1 (*SLC22A12*), a key urate transporter involved in renal proximal tubule urate reabsorption, are thus far inconsistent.[22-26] The splicing variants of glucose transporter 9 (*GLUT9*, *SLC2A9*), an electrogenic hexose transporter, mediate reabsorption of uric acid, glucose, and fructose at the renal proximal tubule epithelial cell, first at the apical membrane, then through the basolateral membrane, and on into the circulation.[27-30] Polymorphisms in *SLC2A9* are associated with a lower serum uric acid, with stronger effects seen in women; they possibly account for 0.5% to 2% of the variance in serum urate concentration in men and 3.4% to 8.8% in women.[23,28,31-33] In five of six populations studied by GWAS, *SLC2A9* polymorphisms were associated with a decreased incidence of self-reported gout, particularly in women.[28,31,32] Indeed, three patients with renal hypouricemia have been identified with

loss-of-function mutations in *SLC2A9*.[29,34] The implication is that certain polymorphisms in *SLC2A9* enhance renal uric acid excretion, lower serum urate levels, and are therefore protective against gout, particularly in women.

A gene product of *ABCG2* (human ATP-binding cassette, subfamily G2) appears to be a secretory urate transporter located in the renal proximal tubule apical border.[35] Polymorphisms in *ABCG2* are associated with a higher serum urate concentration in humans, with a more potent influence in men, potentially accounting for 1.6% to 2.1% of the variance in serum urate concentration in men and 0.5% to 0.8% in women.[24,32] One *ABCG2* polymorphism, rs2231142, has been associated with a higher incidence of gout only in males (odds ratio [OR], 2.03 for self-reported gout).[32] In a transfection model in *Xenopus* oocytes, the common mutation in human *ABCG2* encoded by rs2231142, Q141K, resulted in a 53% decrease in urate transport compared with the wild-type gene product.[35] The implication is that certain polymorphisms in *ABCG2* result in reduced proximal tubule urate secretion, increased serum urate concentrations, and a higher incidence of gout, at least in men.

Because the impact of comorbidities and environmental influences such as diet and lifestyle is so significant in gout, it remains to be seen whether risk contribution from genetic variation is clinically relevant, either directly or because of an unexpected interaction with these other factors. An example of the latter is the potential influence of the urate-fructose/glucose exchange transporter *SCL2A9* polymorphisms on the well-described association of heavy consumption of soft drinks that contain high-fructose corn syrup with elevated serum urate levels and gout.[16,36-38]

## CLINICAL FEATURES

### KEY POINTS

- The three stages of gout are asymptomatic hyperuricemia, acute and intercritical gout, and chronic gouty arthritis.
- A period of asymptomatic hyperuricemia lasts up to 20 years or more before the initial attack of gout or nephrolithiasis.
- The first gout attack generally occurs at age 40 to 60 years in men and after age 60 years in women.
- Many drugs, especially diuretics, raise serum urate levels and predispose people to gout attacks.
- Most attacks of gout, especially early in the course of the disease, are monoarticular, with a predilection for the first metatarsophalangeal joint (podagra). The attacks have a characteristic abrupt and painful onset.
- The differential diagnosis for acute gout is usually infectious arthritis or other crystal-induced synovitis, particularly pseudogout.
- Ultrasonography appears to be a useful adjunct in the diagnosis of acute and chronic gout.
- In untreated or undertreated people, chronic gout is characterized by the development of tophi and progressive joint damage.

Throughout its natural history, gout passes through three stages: (1) asymptomatic hyperuricemia, (2) episodes of acute gouty arthritis separated by asymptomatic intervals (termed *intercritical* or *interval gout*), and (3) chronic gouty arthritis, the period when tophi often become apparent.

The basic pattern of clinical gout begins with acute attacks of intensely painful arthritis. The first attack is usually monoarticular and associated with few constitutional symptoms. Later, attacks may become polyarticular and are associated with fever. Attacks vary in duration but are time limited. Over time, attacks recur at shorter intervals, last longer, and eventually resolve incompletely. This scenario leads to the development of chronic arthritis that slowly progresses to a crippling disease on which acute exacerbations are superimposed.

### Asymptomatic Hyperuricemia

Asymptomatic hyperuricemia is a condition in which the serum urate level is high, but gout—manifested by arthritis or uric acid nephrolithiasis—has not yet occurred. Most people with hyperuricemia remain asymptomatic throughout their lifetimes, although the tendency toward acute gout increases with the serum urate concentration. In the Normative Aging Study, which included only male subjects, the annual incidence rates of gout per 1000 person-years for serum urate levels of 6.0, 6.0 to 6.9, 7.0 to 7.9, 8.0 to 8.9, and greater than 9.0 mg/dL were 0.8, 0.9, 4.1, 8.4, and 49.0, respectively.[13] Based on data from the Framingham Heart Study from 1950-2002, which included 1951 men and 2476 women and had a median follow-up of 28 years, the overall incidence of gout was 4.0 in men and 1.4 in women per 1000 person-years.[39] Relative to serum urate levels, the incidence rates of gout per 1000 person-years for men with levels of less than 5.0, 5.0 to 5.9, 6.0 to 6.9, 7.0 to 7.9, and greater than 8.0 mg/dL were 0.8, 3.4, 8.0, 17.8, and 32.9, respectively ($P$ for trend <0.0001). The incidence rates of gout for women per 1000 person-years with urate levels of less than 5.0, 5.0 to 5.9, 6.0 to 6.9, 7.0 to 7.9, and greater than 8.0 mg/dL were 0.8, 2.5, 4.2, 13.1, and 27.3, respectively ($P$ for trend <0.0001). Thus, even when followed up long term, at least two-thirds of men or women with significant hyperuricemia will not experience gout attacks. The risk of nephrolithiasis increases with the serum urate level and with the magnitude of urinary uric acid excretion. The phase of asymptomatic hyperuricemia ends with the first attack of gouty arthritis or urolithiasis. In most instances, the end of the asymptomatic hyperuricemia phase occurs after at least 20 years of sustained hyperuricemia. Between 10% and 40% of gout subjects have one or more attacks of renal colic before the first articular event.[40]

### Acute Gouty Arthritis

The first attack of acute gouty arthritis usually occurs between age 40 and 60 years in men and after age 60 years in women. Onset before age 25 years should raise the possibility of an unusual form of gout, perhaps one related to a specific enzymatic defect that causes marked purine overproduction, an inherited renal disorder, or the use of certain medications, especially cyclosporine.

A single joint is involved in about 85% to 90% of first attacks, with the first metatarsophalangeal joint being the most commonly affected site.[1,17,41,42] The initial attack is oligoarticular or polyarticular in 10% to 14.5% of cases.[41,42]

Acute gout is predominantly a disease of the lower extremities, but eventually, any joint of any extremity may be involved. Ninety percent of patients experience acute attacks in the great toe at some time during the course of their disease (Figure 95-1A). Next in order of frequency are the insteps, ankles, heels, knees, wrists, fingers, and elbows. Acute attacks rarely affect the shoulders, hips, spine, sacroiliac joints, sternoclavicular joints, acromioclavicular joints, or temporomandibular joints.[43,44] Acute gouty bursitis, tendinitis, or tenosynovitis can also occur.[45,46] Urate deposition and subsequent gout appear to have a predilection for previously damaged joints such as in Heberden's nodes of older women.[47] The differential diagnosis is usually septic arthritis or other crystal-induced arthritis, but a broader differential should be considered in confusing cases (Table 95-1).

Some patients report a history of short, trivial episodes of "ankle sprains," sore heels, or twinges of pain in the great toe before the first dramatic gouty attack. In most patients, however, the initial attack occurs with explosive suddenness and commonly begins at night after the individual has gone to sleep feeling well. Within a few hours of onset, the affected part becomes hot, dusky red, swollen, and extremely tender. Occasionally, lymphangitis may develop. Systemic signs of inflammation may include leukocytosis, fever, and elevation of the erythrocyte sedimentation rate. Radiographs usually show only soft tissue swelling during early episodes.

The course of untreated acute gout is highly variable. Mild attacks may subside in several hours or persist for only a day or two and never reach the intensity described for the classic attack. Severe attacks may last days to weeks. The skin over the joint often desquamates as the erythema subsides. With resolution, the patient becomes asymptomatic and enters the intercritical period.

Certain drugs may precipitate acute gout by either increasing or decreasing serum urate levels acutely. The

occurrence of gout after the initiation of urate-lowering therapy is well established and particularly clinically significant. In fact, the more potent the urate-lowering effect, the more likely there is to be an acute attack.[48] Drug-induced gout as a result of increased serum urate levels occurs on occasion with diuretic therapy, administration of intravenous heparin, and use of cyclosporine.[49-51] Diuretic therapy in elderly people appears to be a particularly important precipitating factor for gouty arthritis. Other provocative factors include trauma, alcohol ingestion, surgery, dietary excess, hemorrhage, foreign protein therapy, infections, and exposure to radiographic contrast material.[52,53] Patients with gout have a 20% risk of experiencing an attack during hospitalization.[54]

The definitive diagnosis of gout is best established by aspiration of the joint and identification of intra-cellular needle-shaped crystals that have negative birefringence upon examination with compensated polarized light microscopy (Figure 95-1C). However, various alternatives have been proposed for a presumptive diagnosis. These alternatives include the triad of acute monoarticular arthritis, hyperuricemia, and a dramatic response to colchicine therapy,[55] a set of criteria proposed by the American College of Rheumatology (ACR; Table 95-2) in 1977,[56] and 10 "propositions" for diagnosis by a European League against Rheumatism (EULAR) panel of experts in 2006 (Table 95-3).[57] (The 2012 ACR Guidelines for Management of Gout assumed that the diagnosis of gout was already clearly established.[58,59]) The use of any of these schemes has limitations. First, although the diagnosis of acute gouty arthritis can be strongly suggested by the typical presentation, not all inflammation of the great toe (podagra) in hyperuricemic patients is caused by gout.[60] Second, some patients with gout are normouricemic at the time of an acute attack, a phenomenon related to alcohol use or a consequence of IL-6 generation by the acute inflammatory process.[61-63] Third, diseases other than gout occasionally can improve with colchicine therapy; these diseases include pseudogout, hydroxyapatite calcific tendinitis, sarcoid arthritis, erythema nodosum, serum sickness, rheumatoid arthritis, and familial Mediterranean fever.[17] Fourth, a recent dual-energy computed tomography (DECT) study confirmed the presence of urate in periarticular structures, especially entheses, during a suspected gout attack, perhaps accounting for the sometimes vexing problem of a joint aspiration that is negative for crystals in spite of a classic presentation.[64] Finally, the simultaneous presence of both gout and septic arthritis can be confusing clinically, with the former masking the latter.[65]

The use of ultrasonography as a means of diagnosing acute and chronic gout is gaining favor. The characteristic finding is a superficial, hyperechoic, irregular band on the surface of articular cartilage, the so-called "double contour sign" or "urate icing," which in one study was seen in 92% of gouty joints but in no joints of patients with other types of arthritis (Figure 95-1E).[66,67] Also characteristic is nonhomogeneous tophaceous material surrounded by an anechoic rim (Figure 95-1F). Further support for ultrasound comes from the demonstration of resolution of these findings in a small number of patients with gout who took urate-lowering therapy and maintained a serum urate level less than or equal to 6 mg/dL for at least 7 months.[68] Recent studies presented in abstract form have indicated excellent concordance between ultrasound readers in identifying changes, along with the presence of these findings even in people with asymptomatic hyperuricemia and the superiority of ultrasound over conventional radiography in detecting gouty erosions.[68-71] Ultrasound now appears to be a technology that will be an important ancillary approach to the diagnosis and treatment of gout. Caution is required, however, because in a recent study, the double contour sign was seen in the joints of approximately 25% of people with asymptomatic hyperuricemia.[72] As for sensitivity, the double contour sign was not present in approximately 40%

**TABLE 95-3** Propositions and Strength of Recommendation: Order According to Topic (Clinical, Urate Crystals, Biochemical, Radiographic, and Risk Factors/Comorbidities)

| | Proposition | SOR (95% CI) VAS 100 | A-B% |
|---|---|---|---|
| 1 | In acute attacks the rapid development of severe pain, swelling, and tenderness that reaches its maximum within just 6-12 hr, especially with overlying erythema, is highly suggestive of crystal inflammation, although not specific for gout | 88 (80-96) | 93 |
| 2 | For typical presentations of gout (such as recurrent podagra with hyperuricemia), a clinical diagnosis alone is reasonably accurate but not definitive without crystal confirmation | 95 (91-98) | 100 |
| 3 | Demonstration of MSU crystals in synovial fluid or tophus aspirates permits a definitive diagnosis of gout | 96 (93-100) | 100 |
| 4 | A routine search for MSU crystals is recommended in all synovial fluid samples obtained from undiagnosed inflamed joints | 90 (83-97) | 87 |
| 5 | Identification of MSU crystals from asymptomatic joints may allow definite diagnosis in intercritical periods | 84 (78-91) | 93 |
| 6 | Gout and sepsis may coexist, so when septic arthritis is suspected, Gram stain and culture of synovial fluid should still be performed even if MSU crystals are identified | 93 (87-99) | 93 |
| 7 | Although serum uric acid levels are the most important risk factor for gout, they do not confirm or exclude gout because many people with hyperuricemia do not experience gout, and during acute attacks, serum levels may be normal | 95 (92-99) | 93 |
| 8 | Renal uric acid excretion should be determined in selected patients with gout, especially those with a family history of young-onset gout, onset of gout when younger than 25 years, or renal calculi | 72 (62-81) | 60 |
| 9 | Although radiographs may be useful for differential diagnosis and may show typical features in chronic gout, they are not useful in confirming the diagnosis of early or acute gout | 86 (79-94) | 93 |
| 10 | Risk factors for gout and associated comorbidity should be assessed, including features of the metabolic syndrome (obesity, hyperglycemia, hyperlipidemia, and hypertension) | 93 (88-98) | 100 |

of subjects despite ultrasound of multiple joints in patients with early-stage gout.[73] MRI is much more sensitive than even ultrasound at detecting gouty erosions in patients with gout whose plain radiographs are normal.[74,75] CT and DECT are also sensitive for the detection of erosions and tophi, and three-dimensional CT may have utility in the quantification of the size of tophi during clinical trials in persons with gout.[75,76]

DECT is accurate for the detection of uric acid renal stones, which have a distinctive radiographic appearance at high versus low kilovolts that allows differentiation of uric acid stones from other types of stones with computer software.[77] In several studies, DECT has been found to be useful in detecting monosodium urate crystal collections in patients with tophaceous gout.[64,78,79] A recent study evaluating DECT for the diagnosis of gout in all spectrums of disease, including early gout, found the sensitivity and specificity of DECT to be 90% and 83%, respectively (Figure 95-2).[64] A caveat is that the false-negative results were generally in patients with acute, recent-onset gout. False-positive results generally occurred in people with advanced knee osteoarthritis. The precise role of DECT and other imaging modalities for the diagnosis of acute gout in a suspicious clinical setting, either without a diagnostic tap or with a tap that reveals no crystals, remains to be seen. Whereas ultrasound has found its way into the rheumatology clinic, concerns about the cost and practicality of DECT, CT, and MRI remain.[80]

## Intercritical Gout

The terms *intercritical gout* and *interval gout* have been applied to the periods between gouty attacks. Although a few people never have a second attack, most experience a second attack within 6 months to 2 years. In the series reported by Gutman,[81] 62% had recurrences within the first year, 16% in 1 to 2 years, 11% in 2 to 5 years, and 4% in 5 to 10 years; 7% had experienced no recurrence in 10 or more years. The frequency of gout attacks usually increases over time in untreated patients. Later attacks have a less explosive onset, may be polyarticular, become more severe, and abate more slowly. Nevertheless, recovery is complete. Radiographic changes may develop during the intercritical period despite no signs of tophi on physical examination. These changes are more likely in patients with more severe hyperuricemia and more frequent acute attacks.[54,82]

The diagnosis of gout in a hyperuricemic patient with a history of acute attacks of monoarthritis may be difficult or inconclusive during the intercritical phase. Aspiration of an asymptomatic joint can be a useful adjunct in the diagnosis of gout if urate crystals are demonstrated. Joint fluids obtained from patients with gout during the intercritical phase revealed monosodium urate crystals in 12.5% to 90% of joints.[83] Such crystals in asymptomatic joints are often associated with mild synovial fluid leukocytosis, which suggests a potential to contribute to joint damage even in the intervals between attacks.

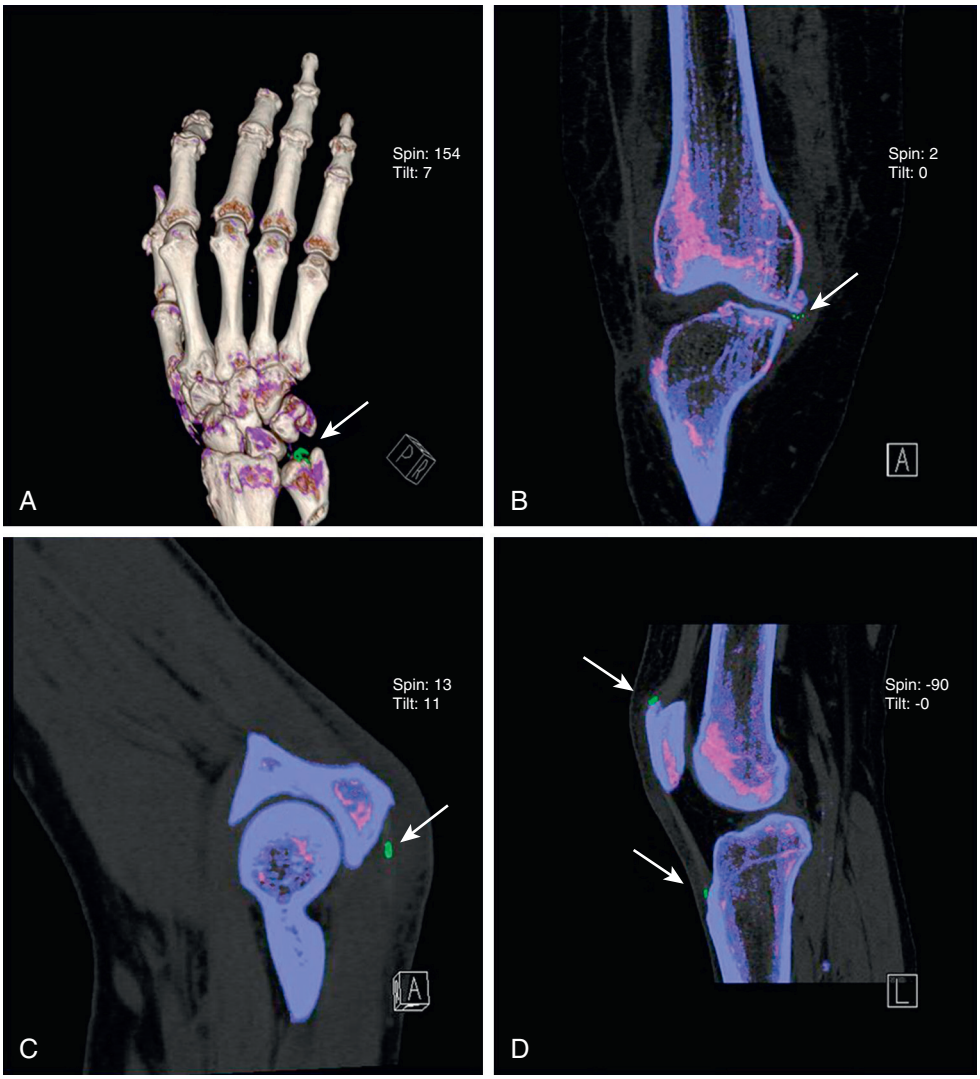

**Figure 95-2** Dual-energy computed tomography images. *Arrows* indicate monosodium urate (MSU) deposition, color coded in *green*, in patients with (**A**) acute gouty arthritis of the wrist (three-dimensional reconstruction image), (**B**) advanced osteoarthritis of the knee, (**C**) elbow pain and swelling, and (**D**) knee pain and swelling. Note that in **B,** the patient did not have active gout, and in **C** and **D**, synovial fluid analysis was initially negative, but post–dual-energy computed tomography ultrasound-guided aspiration was positive for MSU crystals. *(From Bongartz T, Glazebrook KN, Kavros SJ, et al: Dual-energy CT for the diagnosis of gout: an accuracy and diagnostic yield study.* Ann Rheum Dis *74:1072–1077, 2015.)*

## Chronic Gouty Arthritis

Eventually, the patient may enter a phase of chronic polyarticular gout with no pain-free intercritical periods. At this stage, gout is easily confused with other types of arthritis or other conditions.[84-86] The time from the initial attack to the beginning of chronic symptoms or visible tophaceous involvement is highly variable in studies of untreated patients. Hensch[87] reported intervals ranging from 3 to 42 years, with an average of 11.6 years between the first attack and the development of chronic arthritis. Ten years after the first attack, about half the individuals were still free of obvious tophi, and most of the remainder had only minimal deposits. Thereafter the proportion of people with nontophaceous involvement slowly declined, to 28% after 20 years. Two percent of the patients experienced severe crippling disease some 20 years after the initial attack.

The rate of formation of tophaceous deposits correlates with both the degree and the duration of hyperuricemia. The principal determinant is the serum urate level.[54] Gutman[88] found that the mean serum urate concentration was 9.1 mg/dL in 722 patients without tophi, 10 to 12 mg/dL in 456 patients with minimal to moderate tophi, and greater than 11 mg/dL in 11 patients with extensive tophaceous involvement. The rate of tophus formation also increases with the severity of renal disease and the use of diuretics.[89]

Tophaceous gout is the consequence of the chronic inability to eliminate urate as rapidly as it is produced. As the urate pool expands, deposits of urate crystals appear in cartilage, synovial membranes, tendons, soft tissues, and elsewhere. Tophi are rarely present at the time of an initial attack of primary gout.[90,91] They are more likely to be present in people with gout as a result of myeloproliferative diseases, in people with juvenile gout-complicating glycogen storage diseases, in people with Lesch-Nyhan syndrome, or after allograft transplantation in patients treated with cyclosporine.[17,91]

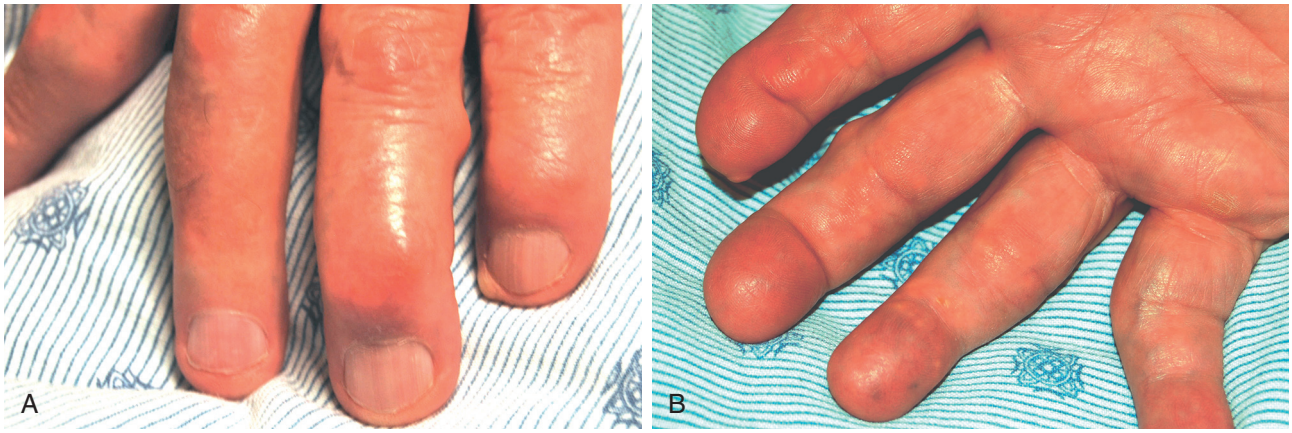

**Figure 95-3** **A,** Dorsal digits of the hand of a patient with tophaceous gout. The involvement of the third distal interphalangeal joint has an appearance similar to inflammatory osteoarthritis or psoriatic arthritis in the appropriate clinical setting. **B,** Palmar view of the same hand revealing obvious "studding" of uric acid deposits.

**Figure 95-4** A uric acid deposit in the prepatellar bursa of the right knee in a patient with tophaceous gout. The patient also has a large effusion in the suprapatellar pouch.

Tophi can occur in a variety of locations. Tophaceous deposits may produce irregular, asymmetric, moderately discrete tumescence of the fingers, hands, knees, or feet (Figures 95-1B, 95-3, 95-4, and 95-5). Tophi also form along the ulnar surfaces of the forearm as saccular distentions of the olecranon bursa (Figure 95-6), in the helix of the ear (Figure 95-7), or as fusiform enlargements of the Achilles tendon (Figure 95-8). The process of tophaceous deposition advances insidiously. Although the tophi themselves are relatively painless, acute inflammation can occur around them. Eventually, extensive destruction of the joints and large subcutaneous tophi may lead to grotesque deformities, particularly of the hands and feet, and to progressive crippling (Figure 95-9). The tense, shiny, thin skin overlying the tophus may ulcerate and extrude white, chalky, or pasty material composed of urate crystals. Secondary infections of tophi are rare.

Typical radiographic changes, particularly erosions with sclerotic margins and overhanging edges of bone, occur with the development of tophi (Figures 95-1D and 95-10).[92] These erosions may be difficult to distinguish from erosions of other causes, but the presence of a thin, overhanging calcified edge is strong evidence of gout. Calcifications can be seen in some tophi, and bony ankylosis may rarely occur. Ultrasonography, MRI, and CT, including DECT, can demonstrate tophi, with DECT providing the most specific images.[64,66-76,78-80,93]

Tophi can produce a marked limitation of joint movement by involvement of the joint structure directly or of a tendon serving the joint. Any joint can be involved, although joints of the lower extremity are primarily affected. Spinal joints do not escape urate deposition,[76,86,94] but acute gouty spondylitis is unusual. Symptoms related to nerve or spinal cord compression by tophi have rarely been observed. Tophi rarely occur in myocardium, valves, cardiac conduction system, various parts of the eye, and the larynx.[95,96]

## ASSOCIATED CONDITIONS

**KEY POINTS**

- **Gout is associated with obesity, hypertriglyceridemia, glucose intolerance and the metabolic syndrome, hypertension, atherosclerosis, and hypothyroidism.**
- **Renal insufficiency is frequently associated with hyperuricemia and gout.**
- **Hyperuricemia is a common cause of nephrolithiasis.**
- **Rarely, chronic hyperuricemia causes urate nephropathy, and acute hyperuricemia can lead to uric acid nephropathy in the tumor lysis syndrome.**
- **Alcohol use, lead intoxication, and cyclosporine treatment are associated with hyperuricemia and gout.**
- **A diagnosis of gout should prompt a search for the co-existence of associated conditions.**

The association of gout with obesity and overeating is well recognized.[97] In 6000 subjects, hyperuricemia was found in only 3.4% of persons with a relative weight at or below the 20th percentile, in 5.7% of subjects between the 21st and 79th percentiles, and in 11.4% of subjects at or above the 80th percentile.[98]

**Figure 95-5** **A,** Chronic tophaceous gout of the great toe involving both the metatarsophalangeal and interphalangeal joints. **B,** Tophaceous gout of the third toe along with extensive onychomycosis could easily be mistaken for a "sausage toe" of psoriatic arthritis.

**Figure 95-6** Uric acid deposits in the olecranon bursa and the extensor forearm in a patient with tophaceous gout.

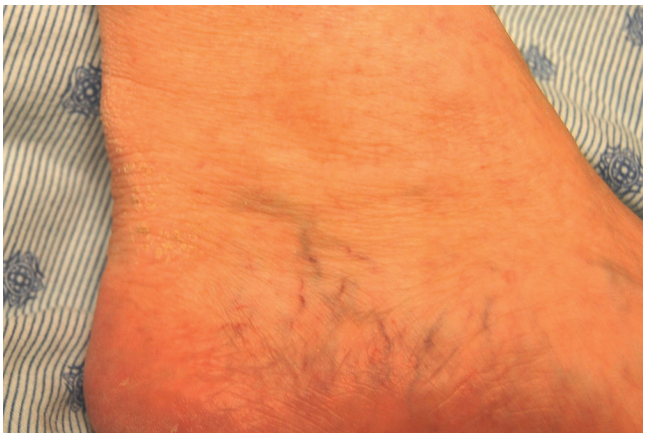

**Figure 95-8** Fusiform tophus of the Achilles tendon above the insertion on the calcaneus.

**Figure 95-7** A tophus in the helix of the ear in a patient with chronic gout.

Hypertriglyceridemia has been reported in 75% to 80% of patients with gout,[99] and hyperuricemia is found in more than 80% of patients with hypertriglyceridemia.[17] However, studies have been unable to show a correlation between serum urate and cholesterol values or a unique lipid phenotype.[100] Patients with gout who drink alcohol excessively have mean serum triglyceride levels that are higher than those of obesity-matched control subjects and of patients with gout who do not drink alcohol.[101]

Hyperuricemia has been reported in 2% to 50% of patients with diabetes mellitus, and gouty arthritis has been reported in fewer than 0.1% to 9% of these patients.[102] Abnormal glucose tolerance tests have been noted in 7% to 74% of patients with gout, depending, in part, on the criteria used.[103]

Hyperuricemia has been reported in 22% to 38% of patients with untreated hypertension. This figure increases to 67% when diuretic therapy and renal disease are present.[17] Hyperuricemia may be an indication of a potential risk for hypertension in adolescent males.[104] Hypertension is present in one-fourth to one-half of patients with classic gout, but the presence of hypertension is unrelated to the duration of gout.[97,98] Elevated serum urate concentrations are associated with increased tubular reabsorption of sodium.[105] The serum urate concentration also correlates inversely with renal blood flow and urate clearance and correlates directly with

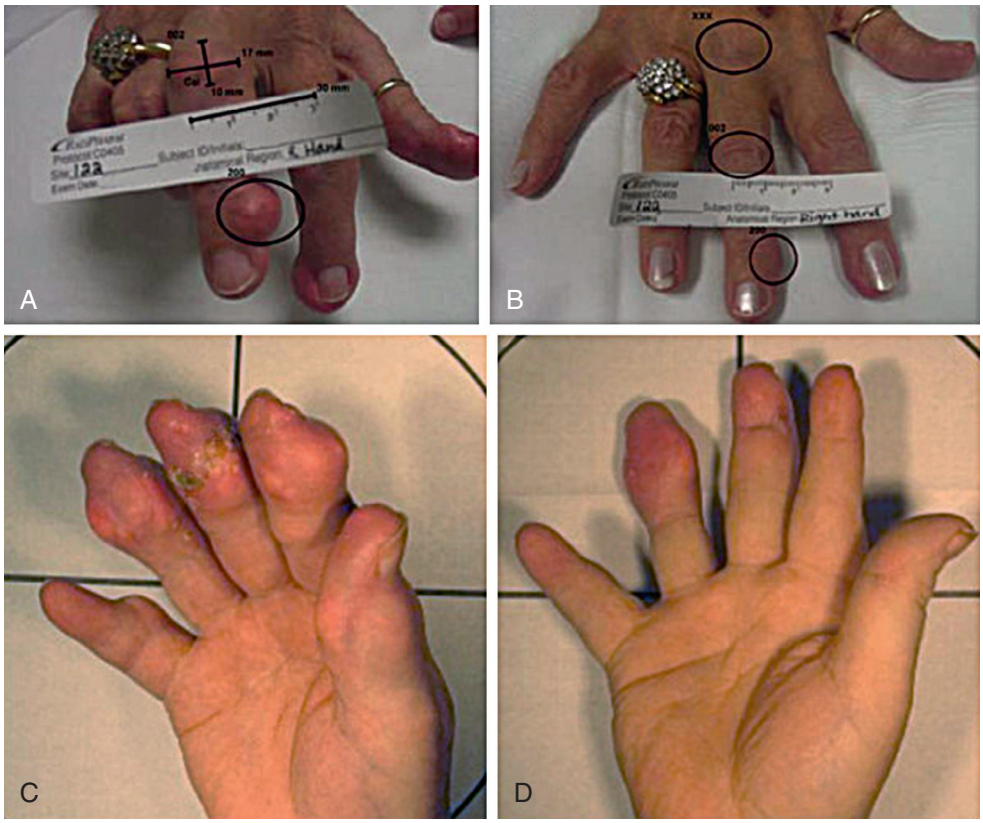

**Figure 95-9** Digital images showing complete resolution of tophi in two patients who received pegloticase biweekly. **A,** Baseline tophus on the medial aspect of the right third distal interphalangeal (DIP) joint in patient 1. **B,** Complete resolution of target tophus at week 13 in patient 1. Note also the reduction in the area of a large tophus on the third proximal interphalangeal joint. **C,** Baseline tophi on the right thumb; on the second, third, and fourth DIP joints with ulcerations; and on the fifth proximal interphalangeal joint of patient 2 after 6 months of treatment with placebo in randomized controlled trials. **D,** Complete resolution of target tophi on four digits in patient 2 after 25 weeks of treatment with twice-monthly pegloticase in an open-label extension study. *(From Baraf HS, Becker MA, Gutierrez-Urena SR, et al: Tophus burden reduction with pegloticase: results from phase 3 randomized trials and open-label extension in patients with chronic gout refractory to conventional therapy.* Arthritis Res Ther *15:R137, 2013.)*

both renovascular and total resistance. Therefore the association between hypertension and hyperuricemia may be related to the reduction of renal blood flow in persons with hypertension. In addition, uric acid causes smooth muscle proliferation in vitro and vascular disease in animal models through a mechanism that involves complex intra-cellular signaling, mitogen-activated protein kinase activation, and platelet-derived growth factor expression.[105,106]

The association between hyperuricemia and the manifestations of atherosclerosis has led to speculation that hyperuricemia is a risk factor for coronary artery disease. Some studies show no clear associations among blood pressure, blood glucose level, or serum cholesterol and serum urate concentration when adjustments are made for the effects of age, sex, and relative weight.[90,98-102,107-110] The serum urate concentrations of persons with coronary heart disease are not significantly different from the mean levels of the population.[110,111] Other studies, however, maintain that hyperuricemia is an independent risk factor for coronary artery disease[112,113] (described in a subsequent section).

The term *metabolic syndrome* has been applied to a cluster of abnormalities, including resistance to insulin-stimulated glucose uptake, hyperinsulinemia, hypertension, and dyslipoproteinemia that are characterized by high levels of plasma triglycerides and high-density lipoprotein cholesterol. Hyperuricemia closely correlates with the degree of insulin resistance[110-116] and therefore is a likely feature of metabolic syndrome. Metabolic syndrome has been associated with coronary artery disease, and hyperuricemia as a component of metabolic syndrome may explain the previously recognized association between coronary artery disease and hyperuricemia. A recent study concluded that the relationship between hyperuricemia and acute myocardial infarction is independent, but patients who experience gouty arthritis are at an increased risk for myocardial infarction. This association could not be explained by renal function, metabolic syndrome, diuretic use, or traditional cardiovascular risk factors.[117] In a prospective study, men with gout had an increased risk of all-cause mortality, and among subjects with pre-existing coronary heart disease, that gout-related increased risk was the result of an elevated risk of cardiovascular death, particularly coronary heart disease.[118] However, a very recent systematic review of the literature concluded that the data supporting an increased risk of developing cardiovascular disease as a result of hyperuricemia or gout are weak and and/or flawed, at best.[119] An up-to-date review recently explored the intricacies of this issue,[120] which will not be laid to rest until an adequately powered, randomized, controlled trial provides a definitive answer.[121]

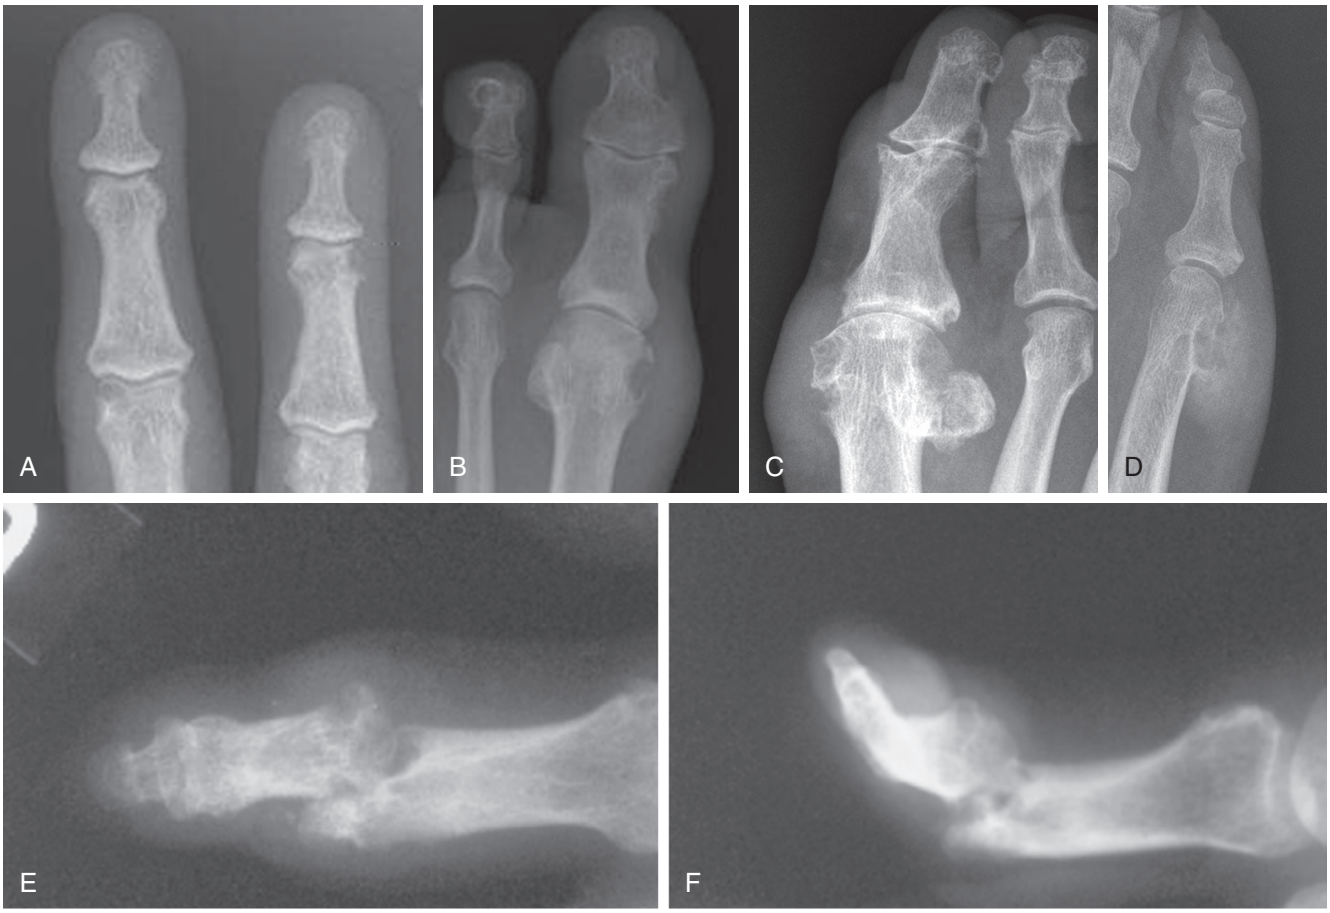

**Figure 95-10** **A** through **F,** Radiographs of damage to joints due to gout. **A,** Erosions at the third proximal interphalangeal and fourth distal interphalangeal joints of the hand. **B,** Discrete punched-out lesion at the first metatarsophalangeal (MTP) joint. **C,** More advanced disease at the first MTP joint with periarticular tophaceous material. **D,** Erosion at the fifth MTP joint. **E** and **F**, Severe destruction with malalignment.

Alcohol consumption has long been associated with hyperuricemia and gout. In susceptible persons, alcohol use can precipitate acute gouty arthritis. An epidemiologic study in Saudi Arabia, where alcohol consumption is rare, revealed an 8.4% prevalence of hyperuricemia but no cases of gout among the study group.[122] Both a decrease in the renal excretion of uric acid and an increase in uric acid production seem to be important factors in this association.[123] Ethanol increases uric acid production by accelerating the turnover of ATP. Among alcoholic beverages, beer may have more potent effects on uric acid production because of its high guanosine content.[14]

A significant increased prevalence of hypothyroidism appears to exist among both female and male patients with gouty arthritis.[124] Hyperuricemia may also be more prevalent in patients with hypothyroidism. Thyroid replacement therapy is associated with a decrease in serum urate concentration caused by an increased uric acid diuresis—a change not explained solely by a change in creatinine clearance.[125] Although the cause of hyperuricemia and gout in patients with hypothyroidism is unknown, it is speculated that urate metabolism is mediated by thyroid-stimulating hormone receptors in extrathyroidal tissues, including the kidney and that these receptors modulate urate homeostasis.

Studies of acutely ill patients in intensive care units indicate that markedly increased serum urate concentrations, in the vicinity of 20 mg/dL, are associated with hypotensive events and a poor prognosis.[126] This finding may be related to two factors. First, ischemic tissue may foster the degradation of ATP to purine end products, thereby enhancing the production of urate. The finding of increased plasma ATP degradation products associated with hyperuricemia and adult respiratory distress syndrome supports this possibility.[127] Second, the conversion of hypoxanthine to uric acid by xanthine oxidase during ischemia produces oxidant radicals, which are themselves associated with tissue injury.[128] It is possible that inhibition of xanthine oxidase with allopurinol may be a useful therapy in this setting.

Maternal serum urate concentrations normally decrease during pregnancy until the 24th week and then increase until 12 weeks after delivery.[129] An increase in the serum urate level occurs in pre-eclampsia and toxemia of pregnancy as a result of a decrease in the renal clearance of urate.[130] Perinatal mortality is markedly increased when maternal plasma urate levels are raised, usually in association with early-onset pre-eclampsia. The highest mortality rate is seen with serum urate concentrations higher

than 6 mg/dL and diastolic blood pressures greater than 110 mm Hg. Labor itself is associated with an increased serum urate level, and it remains elevated for 1 to 2 days after delivery.

Gout is rarely seen in patients with rheumatoid arthritis, systemic lupus erythematosus, or ankylosing spondylitis.[44,131-133] The basis for the decreased concurrence of these disorders is unclear, although the long-term use of NSAIDs or corticosteroids may mask the clinical features of gout in some of these patients.

## Renal Disease

After gouty arthritis, renal problems appear to be the most frequent complication of hyperuricemia. Approximately 20% to 40% of patients with gout have albuminuria, which is usually mild and often intermittent. Hyperuricemia alone may be implicated as the cause of chronic kidney disease only when the concentration of urate chronically exceeds 13 mg/dL in men or 10 mg/dL in women.[134] Before the routine treatment of asymptomatic hypertension, renal failure accounted for 10% of the deaths in patients with gout. Whether moderate hyperuricemia has a direct harmful effect on renal function is unclear. Some evidence suggests that urate damages the kidneys and leads to hypertension.[105,106]

The term *urate nephropathy* is used to describe the deposition of urate crystals in the interstitium of the medulla and pyramids, with a surrounding giant cell reaction—a distinctive histologic finding characteristic of the gouty kidney (Figure 95-11). Factors such as coexistent hypertension, chronic lead exposure, ischemic heart disease, and primary pre-existing renal insufficiency probably play important roles in the pathogenesis of this disease. Although urate nephropathy appears to exist as a distinct entity, it was not generally believed to be an important contributor to renal function in most patients with gout.[17,135] However, recent studies indicate that hyperuricemia may well play a significant role in renal function, and sustained urate-lowering therapy appears to impede renal function decline in patients with gout.[136]

In contrast, *uric acid nephropathy* is the term used to describe acute renal failure resulting from the precipitation of large quantities of uric acid crystals in the collecting ducts and ureters. This complication most commonly occurs in patients with leukemia and lymphoma as a result of rapid malignant cell turnover, often during chemotherapy.[137,138] This syndrome (also termed *acute tumor lysis syndrome*) has been more clearly defined as hyperuricemia, lactic acidosis, hyperkalemia, hyperphosphatemia, and hypocalcemia and is most commonly observed in patients with aggressive, rapidly proliferating tumors, including lymphoproliferative disorders and metastatic medulloblastoma. Uric acid nephropathy is less commonly found with other neoplasms, after epileptic seizures, after vigorous exercise with heat stress, and after angiography and coronary artery bypass surgery.[17]

In the tumor lysis syndrome, the large amount of nucleic acid in nucleotides liberated with massive cytolysis is converted rapidly to uric acid. Typically, marked hyperuricemia is present, with a mean serum urate level of 20 mg/dL (range, 12 to 80 mg/dL). The pathogenesis of acute renal failure in uric acid nephropathy is related to the precipitation of uric acid in the distal tubules and collecting ducts, the sites of maximal acidification and concentration of urine. Oliguria, or even anuria, and azotemia may occur. "Gravel" or "sand" may be noted in the urine. The ratio of urinary uric acid to creatinine in these patients typically exceeds 1; in patients with most other causes of acute renal failure, the ratio is $0.4 \pm 0.3$.[138]

Nephrolithiasis occurs in 10% to 25% of patients with primary gout, a prevalence greater than that in the general population. The likelihood of stones in a given patient with gout increases with the serum urate concentration and with amounts of urinary uric acid excretion.[41,139] It exceeds 50% with a serum urate value above 13 mg/dL or with urinary uric acid excretion rates in excess of 1100 mg every 24 hours.

Uric acid calculi account for approximately 10% of all stones in patients in the United States; elsewhere, rates range from as low as 5% up to 40% in Israel and Australia, respectively.[17] Uric acid stones can occur in patients with no history of gouty arthritis, and only 20% in this group are hyperuricemic. Other renal stone disease is associated with hyperuricemia and gout. Subjects with gout also have an increased incidence of stones that contain calcium. In addition, about 30% of patients with recurrent calcium stone disease have either an increased urinary uric acid excretion rate or hyperuricemia. A causative link between uric acid and recurrent calcium oxalate stones is provided by reports of reduced stone frequency in patients treated with allopurinol.

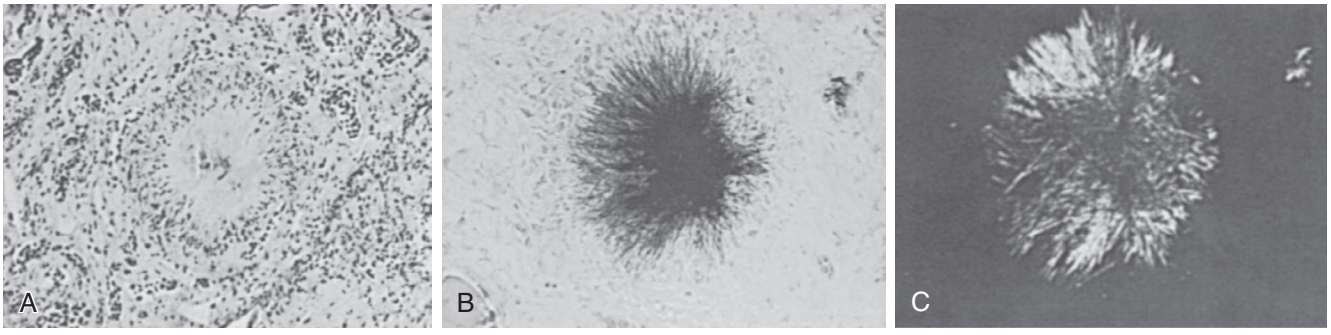

**Figure 95-11** **A,** Urate deposit in the medulla of the kidneys as seen in an alcohol-fixed section stained with hematoxylin-eosin (×250). **B,** Adjacent section of the deposit stained with methenamine silver (×250). **C,** Adjacent section of the same deposit seen with polarized light (×250).

Finally, the report of uric acid as the major constituent of a stone obtained from a patient with no apparent abnormalities of uric acid metabolism should suggest the possibility that the constituent is actually 2,8-dihydroxyadenine and that the patient has adenine phosphoribosyltransferase deficiency.[140] X-ray diffraction is required to distinguish uric acid from 2,8-dihydroxyadenine.

Familial juvenile hyperuricemic nephropathy (FJHN), sometimes called *familial juvenile gouty nephropathy*, was first described in the 1960s.[141] This disorder is inherited as an autosomal dominant trait with a high degree of penetrance and is usually associated with gout. Renal disease typically develops in the second decade of life and progresses to end-stage renal failure by midlife.[142-144] Histologic examination of kidney tissue reveals tubulointerstitial inflammation and splitting of thickened tubular basement membranes. The primary diagnostic criterion is a reduced fractional excretion of urate (defined as uric acid clearance factored by creatinine clearance × 100 equal to 5% or less; normal is 8% to 18%).[145] The dramatically low fractional excretion of urate and the early onset of disease are conspicuous characteristics of FJHN and distinguish it from other autosomal dominant hyperuricemic disorders that usually appear later in life (Table 95-4). Genotype mapping has linked the gene for FJHN to chromosome 16p12-p11.[143]

Autosomal dominant medullary cystic kidney disease (ADMCKD) is another hereditary nephropathy that usually includes gout among its constellation of symptoms. The onset of renal dysfunction occurs later than in persons with FJHN. Renal histology reveals numerous corticomedullary and intramedullary cysts in the kidneys and increased medullary connective tissue. At least two loci appear to be responsible for ADMCKD. One, termed ADMCKD1, is located on chromosome 1; the other, ADMCKD2, is a 16p locus. ADMCKD2 and FJHN loci map to approximately the same region of chromosome 16p.[146]

The chromosome 16p12 locus that harbors the candidate interval for FJHN and ADMCKD2 contains six candidate genes, including the uromodulin gene *(UMOD)*.[147-149] *UMOD* encodes the Tamm-Horsfall protein, a glycosyl phosphatidylinositol–anchored glycoprotein localized to the thick ascending limb of the loop of Henle. Amorphous deposits of uromodulin are present in the renal interstitium of patients with medullary cystic kidney disease.[150] Four different mutations in exon 4 have been identified in the *UMOD* gene. Because mutations in the same gene are responsible for both FJHN and ADMCKD, the two entities appear to be allelic variants in *UMOD* that cause decreased urinary concentrations of Tamm-Horsfall protein, with resulting hyperuricemia and progressive renal failure.[151]

**TABLE 95-4** Genetics of Renal Diseases Associated with Gout

| Condition | Inheritance | Chromosomal Location | Gene |
|---|---|---|---|
| FJHN | AD | 16p12.3<br>17cenq21.3 | Uromodulin<br>HNF-1β |
| MCKD type 1 | AD | 1q21 | ? |
| MCKD type 2 | AD, AR | 16p12.3 | Uromodulin |

AD, Autosomal dominant; AR, autosomal recessive; FJHN, familial juvenile hyperuricemic nephropathy; HNF, hepatic nuclear factor; MCKD, medullary cystic kidney disease.

## Lead Intoxication

Hyperuricemia and gout are well-recognized complications of chronic lead intoxication, with the prevalence of gout in patients with plumbism ranging between 6% and 50%.[152] Although a renal defect is recognized, it has not been well defined.[153,154] Some patients with primary gout have increased blood lead levels compared with age- and sex-matched control subjects, despite the absence of a history of overt lead exposure.[155] This finding suggests that occult chronic lead intoxication may play a causative role in some cases of primary gout (up to 36% of some gout populations).[152] In addition, patients with gout who have renal impairment seem to have an increased quantity of mobilized lead compared with gouty patients who have normal renal function.[156] These observations suggest an important role for lead in the pathogenesis of gouty nephropathy.

## Cyclosporine-Induced Hyperuricemia and Gout

Cyclosporine interferes with the renal excretion of uric acid. Hyperuricemia and gout occur with increased frequency among transplant recipients treated with cyclosporine and are even more common when diuretics are used concomitantly.[91,157] However, serum urate levels do not correlate directly with cyclosporine levels or with the degree of hypertension or renal insufficiency. The onset of gout may occur soon after transplantation, with a mean of about 17 months. Gout attacks may be typical and monoarticular, or they may affect unusual sites such as the shoulder, hip, or sacroiliac joints. Polyarticular attacks and an accelerated course, with early development of tophi, may also be observed. Nephrolithiasis develops in about 3% of patients who undergo a renal transplant. All calculi from patients treated with azathioprine are composed of calcium compounds, whereas 60% of the calculi from people treated with cyclosporine contain uric acid.[158]

# CLASSIFICATION OF HYPERURICEMIA AND GOUT

**KEY POINTS**

**Primary hyperuricemia and gout are caused by decreased renal uric acid excretion in more than 90% of affected patients and overproduction of urate in less than 10% of affected patients.**

**Secondary hyperuricemia and gout are usually related to decreased renal urate clearance as a direct or indirect consequence of the primary disease process.**

**Four known inborn errors of purine metabolism with overproduction of urate account for less than 1% of cases of secondary hyperuricemia and gout.**

The concentration of urate in body fluids is determined by the balance between production and elimination. Accordingly, hyperuricemia may be caused by an excessive rate of

**TABLE 95-5** Classification of Hyperuricemia and Gout

| Type | Metabolic Disturbance | Inheritance |
|---|---|---|
| **Primary** | | |
| **Molecular Defects Undefined** | | |
| Underexcretion (90% of primary gout) | Not established | Polygenic |
| Overproduction (10% of primary gout) | Not established | Polygenic |
| **Associated with Specific Enzyme Defects** | | |
| PRPP synthetase variants; increased activity | Overproduction of PRPP and uric acid | X-linked |
| HPRT deficiency, partial | Overproduction of uric acid; increased purine biosynthesis de novo driven by surplus PRPP; Kelley-Seegmiller syndrome | X-linked |
| **Secondary** | | |
| **Associated with Increased Purine Biosynthesis De Novo** | | |
| HPRT deficiency, "virtually complete" | Overproduction of uric acid; increased purine biosynthesis de novo driven by surplus PRPP; Lesch-Nyhan syndrome | X-linked |
| Glucose-6-phosphatase deficiency or absence | Overproduction plus underexcretion of uric acid; glycogen storage disease type I (von Gierke's disease) | Autosomal recessive |
| Fructose-1-phosphate aldolase deficiency | Overproduction plus underexcretion of uric acid | Autosomal recessive |
| **Associated with Increased ATP Degradation** | | |
| Associated with increased nucleic acid turnover | Overproduction of uric acid | Most not familial |
| Associated with decreased renal excretion of uric acid | Decreased filtration of uric acid, inhibited tubular secretion of uric acid, or enhanced tubular reabsorption of uric acid | Some autosomal dominant; some not familial; most unknown |
| **Idiopathic** | | Unknown |

ATP, Adenosine triphosphate; HPRT, hypoxanthine phosphoribosyltransferase; PRPP, phosphoribosylpyrophosphate.

urate production, a decrease in the renal excretion of uric acid, or a combination of both events.

Hyperuricemia and gout may be classified as follows (Table 95-5):

- Primary: These cases appear to be innate—that is, they are neither secondary to an acquired disorder nor the result of a subordinate manifestation of an inborn error that leads initially to a major disease, unlike gout. Some but not all cases of primary gout have a genetic basis.
- Secondary: These cases develop in the course of another disease or as a consequence of drug use.
- Idiopathic: In these cases, a more precise classification cannot be assigned.

Further subdivisions within each major category are based on the identification of overproduction, underexcretion, or both as being responsible for the hyperuricemia. Evidence of overproduction of urate is provided by determination of the 24-hour urinary uric acid excretion. For adults ingesting a purine-free diet, a total excretion of up to 600 mg/day is considered to be within the normal range.[159] For patients consuming regular diets, a value in excess of 1000 mg/day is clearly abnormal and an indication of overproduction, and values between 800 and 1000 mg/day are considered borderline. It has been suggested that overproduction of uric acid can be assessed simply by determining the ratio of uric acid to creatinine in the urine or the $C_{urate}/C_{creatinine}$ ratio. However, comparison of these two ratios with the 24-hour urinary uric acid excretion reveals a poor correlation in most patients.[160,161] Exceptions include patients with specific enzymatic deficiencies or with rapid cell lysis during chemotherapy for leukemia or lymphoma.

## Primary Gout

Renal mechanisms are responsible for hyperuricemia in most cases of gout. Genetic factors exert an important control in the renal clearance of urate.[162] A careful comparison of uric acid clearances and excretion rates over a wide but comparable range of filtered loads of urate indicates that most gouty subjects have a lower ratio of urate-to-inulin clearance ($C_{urate}/C_{inulin}$ ratio) than do nongouty subjects.[159,162,163] The excretion rates and the capacity of the excretory mechanism for uric acid are the same for people with and without gout. The excretion curve, however, is shifted. Subjects with gout require serum urate values 2 or 3 mg/dL higher than those of control subjects to achieve equivalent uric acid excretion rates. Theoretically, the shift in the excretion curve in subjects with gout may result from reduced filtration of urate, enhanced reabsorption, or decreased secretion. Patients classified as exhibiting an overproduction of uric acid represent less than 10% of the gouty population.

## Secondary Gout

Numerous secondary causes of hyperuricemia and gout can be attributed to a decrease in the renal excretion of uric acid. A reduction in the glomerular filtration rate leads to a decrease in the filtered load of urate and, consequently, to hyperuricemia. Patients with renal disease are hyperuricemic on this basis. Other factors such as decreased secretion of urate have been postulated in patients with some types of renal disease (e.g., polycystic kidney disease and lead nephropathy).

Diuretic therapy currently represents one of the most important causes of secondary hyperuricemia in humans. Diuretic-induced volume depletion leads to a decreased filtered load and enhanced tubular reabsorption of urate. A number of other drugs lead to hyperuricemia by a renal mechanism. These agents include low-dose aspirin, pyrazinamide, nicotinic acid, ethambutol, ethanol, and cyclosporine.

Decreased renal excretion of uric acid is thought to be an important mechanism for the hyperuricemia associated with several disease states. Volume depletion may be an important factor in patients with hyperuricemia that is associated with adrenal insufficiency or nephrogenic diabetes insipidus. An accumulation of organic acids leads to hyperuricemia, which is the case in starvation, alcoholic ketosis, diabetic ketoacidosis, maple syrup urine disease, and lactic acidosis of any cause (e.g., hypoxemia, respiratory insufficiency, chronic beryllium disease, and acute alcohol intoxication). The renal bases of the hyperuricemia in conditions such as chronic lead intoxication, hypoparathyroidism, pseudohypoparathyroidism, and hypothyroidism remain unclear.

Secondary gout can also result from urate overproduction. Four specific defects cause urate overproduction as a consequence of accelerated de novo purine biosynthesis: hypoxanthine phosphoribosyltransferase deficiency, phosphoribosylpyrophosphate synthetase overactivity, glucose-6-phosphatase deficiency, and fructose-1-phosphate aldolase deficiency.

## TREATMENT

### KEY POINTS

**Asymptomatic hyperuricemia generally is not treated with specific urate-lowering therapy, but identification of this condition should lead to a search for the cause and/or associated conditions.**

**Episodes of acute gouty arthritis can be treated with colchicine, NSAIDs, adrenocorticotropic hormone, and systemic or intra-articular steroids.**

**Prophylaxis against acute attacks with colchicine or NSAIDs can be effective but does not change the underlying process in the absence of concomitant urate-lowering therapy.**

**Starting urate-lowering therapy after a single attack of gout remains debatable, but recurrent attacks of gout, urate nephrolithiasis, tophaceous gout, and/or evidence of gout-induced joint damage are all accepted indications for this therapy.**

**Xanthine oxidase inhibitors and uricosuric agents are effective at lowering serum urate levels in most patients.**

**Uricases such as pegloticase should be reserved for refractory tophaceous gout.**

**A serum urate of less than 6 mg/dL is the target of therapy.**

**Prophylaxis with colchicine, NSAIDs, or, less preferably, systemic steroids should be continued for at least 6 months after initiation of urate-lowering therapy.**

**Long-term compliance with the treatment regimen remains a major issue in gout; forming a therapeutic alliance with the patient is critical.**

**Lifestyle modifications, especially reduced alcohol consumption, may help somewhat in the control of gout but are more important for the management of associated conditions such as obesity and hyperlipidemia.**

The therapeutic aims in gout are as follows (Figure 95-12):

- To terminate the acute attack as promptly as possible
- To prevent recurrences of acute gouty arthritis
- To prevent or reverse complications of the disease resulting from the deposition of sodium urate or uric acid crystals in joints, kidneys, or other sites

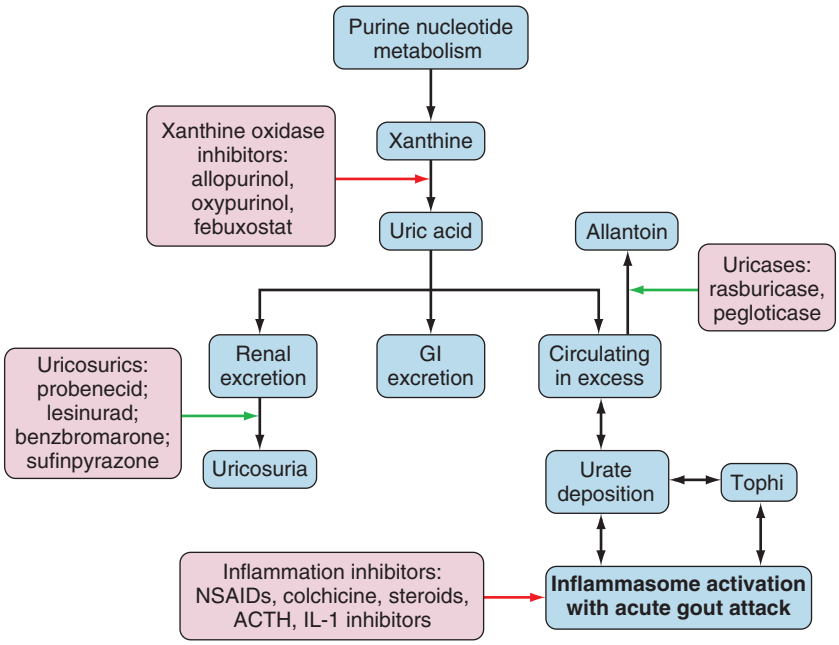

**Figure 95-12** Treatment options for gout, including inhibitors of inflammation used for acute attacks and the available approaches for lowering serum urate when appropriate. Some inflammation inhibitors may also be used for prophylaxis when initiating urate lowering therapy. See text for details. *Red arrows* indicate inhibitory effects; *green arrows* indicate promoting effects. ACTH, Adrenocorticotropic hormone; GI, gastrointestinal.

- To prevent or reverse conditions associated with gout that are deleterious, such as obesity, hypertriglyceridemia, and hypertension

## Asymptomatic Hyperuricemia

The presence of hyperuricemia is rarely an indication for specific urate-lowering therapy. Rather, upon diagnosing hyperuricemia, the following questions should be addressed:

- What is the cause of the hyperuricemia?
- Are associated findings present?
- Has damage to tissues or organs occurred as a result of the hyperuricemia?
- What, if anything, should be done?

Hyperuricemia may be the initial clue to the presence of a previously unsuspected disorder. In 70% of hyperuricemic patients, an underlying cause can be readily determined by history and physical examination. The nature of the underlying cause may be useful in predicting the potential consequences, if any, of the elevated serum urate concentration. Therefore an underlying cause should be sought in every patient with hyperuricemia.

Whether to treat hyperuricemia uncomplicated by articular gout, urolithiasis, or nephropathy is an exercise in clinical judgment, and universal agreement is lacking. When considering whether to treat asymptomatic hyperuricemia with urate-lowering agents, the following data are pertinent:

- Although there are intriguing data from animal models to the contrary,[106,107,164] no good evidence in humans has been found that renal function is adversely affected by elevated serum urate concentrations.
- The renal disease that accompanies hyperuricemia is most often related to inadequately controlled hypertension.
- Although debate exists regarding whether hyperuricemia is an independent risk factor for coronary artery disease,[110-113] thus far there is no evidence that correction of hyperuricemia has an effect on the development of heart disease (as previously discussed).

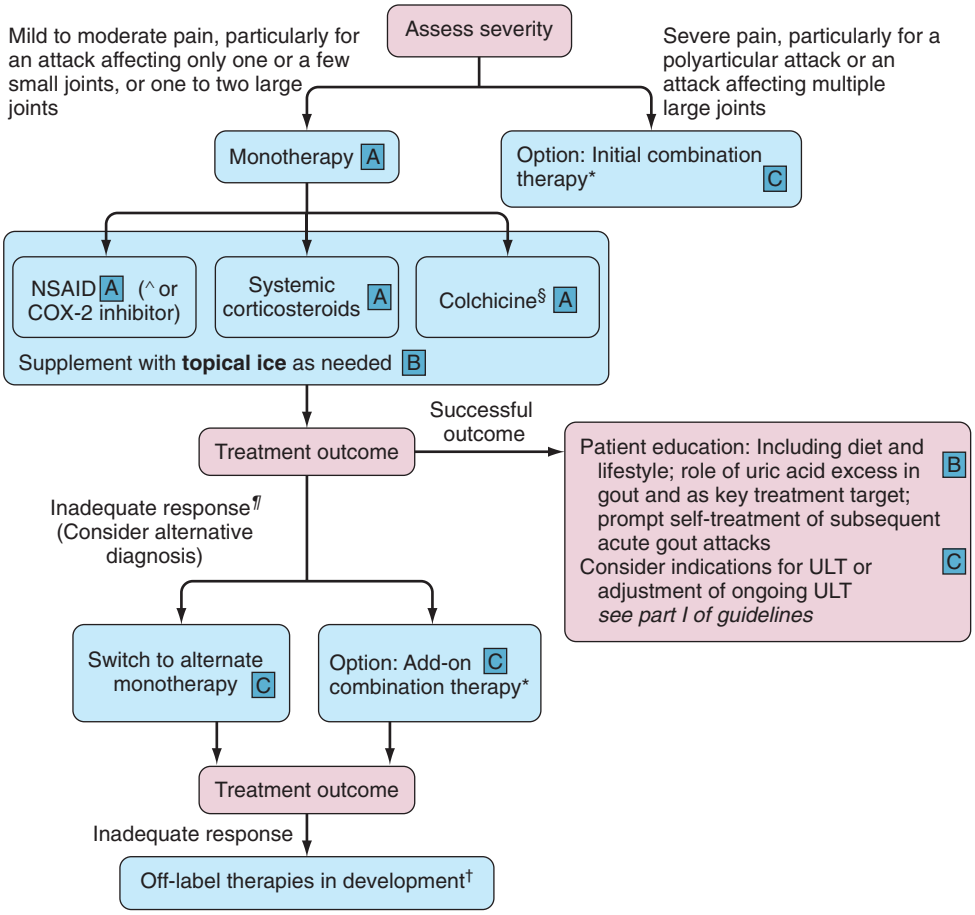
Thus it seems prudent to refrain from treating hyperuricemia with specific urate-lowering agents until symptoms develop. Rare exceptions are made for people who have a known hereditary cause of uric acid overproduction or who are at risk for acute uric acid nephropathy.

The cause of hyperuricemia should be determined and that any associated factors related to the process, such as obesity, hyperlipidemia, alcoholism, and, especially, hypertension, be addressed. Fenofibrate and losartan might be appropriate agents for the treatment of hypertriglyceridemia and hypertension, respectively, in hyperuricemic people because each has modest uricosuric effects.[165,166]

## Acute Gouty Arthritis

The acute gouty attack may be successfully terminated by any of several drugs. For practical purposes, the choice in most situations is among colchicine, an NSAID, a corticosteroid preparation, or adrenocorticotropic hormone (ACTH). In response to the recognition of the critical role that IL-1β plays in the initiation of gout attacks, trials of biologic inhibitors of IL-1β for both the treatment and prophylaxis of acute gout have been undertaken with promising results.[167-171] Although approved for the treatment of TNF receptor–associated periodic fever syndromes, these expensive agents have not been approved for gout in the United States at this writing. In the European Union, canakinumab, a humanized, monoclonal anti–IL-1β antibody, is available for the treatment of acute gout under certain circumstances. The 2012 ACR Guidelines for the Management of Gout include an algorithm for treatment of the acute gout attack[59] (Figure 95-13).

The timing of the initiation of therapy is more important than the choice of drug for acute gout.[172] With any of these agents, the sooner the drug is started, the more rapidly a complete response will be attained. Generally, colchicine is preferred for patients in whom the diagnosis of gout is not confirmed, whereas NSAIDs are preferred when the diagnosis is secure. If a patient cannot take medications by mouth or has active peptic ulcer disease, the choice is among intra-articular glucocorticoids, parenteral glucocorticoids, or ACTH. Local application of ice packs may help control the pain of an acute attack.[173] In some cases, analgesics, including narcotics, may be added as well. In almost all cases, drugs that affect serum urate concentrations, including urate-lowering agents, should not be stopped during an acute attack. Whether such drugs should be started during an acute attack is debated. Because a sudden lowering of serum urate levels is known to precipitate acute attacks, an inflammatory reaction that is already in progress may be substantially worsened by a major drop in the serum urate concentration. However, one study suggests that in selected patients this outcome does not occur, provided the patient is also receiving treatment for the acute flare.[174]



### Colchicine

Traditionally, the oral dosing schedule for colchicine was 0.5 or 0.6 mg taken hourly until one of three outcomes occurred: joint symptoms eased; nausea, vomiting, or diarrhea developed; or the patient had taken a maximum of 10 doses. If 10 doses were taken without benefit, the clinician questioned the accuracy of the diagnosis. Many clinicians have recommended for some time that doses be taken every 2 to 6 hours to reduce the incidence of adverse effects.[175] In 2009 the U.S. Food and Drug Administration (FDA) approved the first single-ingredient oral colchicine product for the treatment of acute gout flares and the prophylaxis of gout flares, as well as for familial Mediterranean fever in adults and children 4 years or older. The FDA ordered a halt to the marketing of unapproved single-ingredient colchicine preparations other than this product, which led to a dramatic increase in cost. The new recommendation for colchicine is a low-dose regimen of 1.2 mg, followed by 0.6 mg in 1 hour, for a total of 1.8 mg per attack. That protocol is based on the results of a randomized controlled trial of 184 patients with acute gout flares of less than 12 hours' duration that compared low-dose colchicine (in 74 patients) with high-dose colchicine (4.8 mg total over 6 hours in 52 patients) and with placebo (in 58 patients), with a primary endpoint of at least a 50% reduction in pain within 24 hours.[176] The low-dose approach resulted in comparable peak plasma concentrations and early gout flare

MANAGEMENT OF AN ACUTE GOUT ATTACK

General principles:

- Acute gouty arthritis attacks should be treated with pharmacologic therapy C#
- To provide optimal care, pharmacologic treatment should be initiated within 24 hours of acute gout attack onset C
- Ongoing pharmacologic ULT should not be interrupted during an acute gout attack C

#Evidence grades for recommendations:
**Level A**: Supported by multiple (i.e., more than one) randomized clinical trials or meta-analyses
**Level B**: Derived from a single randomized trial, or nonrandomized studies
**Level C**: Consensus opinion of experts, case studies, or standard of care
*§Colchicine was recommended as an appropriate option for acute gout if started within 36 hours of symptom onset.*
*^Selective COX-2 inhibition with agents available outside the United States, such as etoricoxib (Evidence A) was recommended as an option in patients with GI contraindications or intolerance to NSAIDs, but selective COX-2 inhibition shares many adverse events with NSAID therapy. COX-2 inhibition therapy with celecoxib (Evidence B) requires high doses and has unclear risk-benefit ratio at this time.*
*¶**Inadequate response** is defined as*
***<20**% improvement in pain score within **24 hours** or*
***<50**% at ≥**24 hours***
**See original referenced article for details.*
*†Off-label use of biologic IL-1 inhibitor treatment has been investigated for acute gout when nonbiologic therapeutic categories are ineffective or contraindicated, but this approach is not approved for gout by medical regulatory agencies at the time this is written.*

**Figure 95-13** Overview of management of an acute gout attack. COX-2, Cyclooxygenase-2; ULT, urate-lowering therapy. *(Modified from Khanna D, Fitzgerald JD, Khanna PP, et al: 2012 American College of Rheumatology guidelines for management of gout. Part 2: therapy and anti-inflammatory prophylaxis of acute gouty arthritis.* Arthritis Care Res *64:1447, 2012.)*

control with much fewer adverse effects, particularly diarrhea and vomiting, compared with the high-dose approach. It should be noted that these patients started treatment within 12 hours of attack onset, and there was still a greater than 30% failure to achieve the primary endpoint in both treatment arms. The appropriate dosing of colchicine for attacks of greater duration remains unclear. The low-dose recommendations are in line with those of a EULAR panel of experts.[177] The 2012 ACR Guidelines recommend starting with 1.2 mg, followed by 0.6 mg 1 hour later, and then 0.6 every 12 hours until the attack has subsided.[58] This regimen can then be followed by 0.6 mg once or twice daily for prophylaxis as needed. As always, dosages should be adjusted for renal insufficiency.

The dosing for prophylaxis of 0.6 mg once or twice a day is recommended on the basis of two randomized trials.[178,179] Patients with severe renal insufficiency should be started at 0.3 mg a day. The marketing of unapproved, injectable colchicine was prohibited by the FDA in 2008 because of an unacceptable safety profile, with the potential for serious adverse events, including death, with intravenous administration.

Peak plasma concentrations of colchicine occur within 2 hours of oral administration. Although its plasma half-life is 4 hours, levels can be detected in neutrophils 10 days after ingestion. Colchicine has a low therapeutic index, with steady-state plasma concentrations after acute treatment ranging from 0.5 to 3 ng/mL and toxic effects occurring at approximately 3 ng/mL.[180] Therefore, in most patients, the adverse effects precede or coincide with the improvement in joint symptoms. These adverse effects develop in 50% to 80% of patients using the old, high-dose regimen and include increased peristalsis, cramping abdominal pain, diarrhea, nausea, and vomiting. The drug must be stopped promptly at the first sign of gastrointestinal adverse effects.[181] The FDA prescribing guidelines recommend not using colchicine or reducing the dose in patients who take inhibitors of cytochrome P450 3A4 and of P-glycoprotein. Clarithromycin, erythromycin, cyclosporine, and disulfiram can all have serious interactions with colchicine.[182,183] In addition, the risk of myopathy is increased with the concomitant use of colchicine and other drugs with potential myotoxicity, such as statins and hydroxychloroquine.

Colchicine derives its effectiveness from its ability to interfere with acute inflammatory reactions in a variety of ways. Colchicine blocks the processing of IL-1β[184] and inhibits E-selectin–mediated adhesiveness to neutrophils.[185] Its action diminishes neutrophil L-selectin expression, random motility, chemotaxis, phospholipase $A_2$ activation, and IL-1 expression, as well as the stimulated elaboration of platelet-activating factor, crystal-induced chemotactic factor, and leukotriene $B_4$. Colchicine also inhibits endothelial cell intercellular adhesion molecule-1 (ICAM-1) expression, mast cell histamine release, and neutrophil degranulation and downregulates TNF receptors on macrophages and endothelial cells.

### Nonsteroidal Anti-inflammatory Drugs

In a patient with an established diagnosis of uncomplicated gout, the preferred agent is an NSAID, with indomethacin being the traditional choice. Although this drug may be effective in doses as low as 25 mg four times a day, an initial dose of 50 to 75 mg, followed by 50 mg every 6 to 8 hours, with a maximum dose of 200 mg in the first 24 hours, has generally been recommended. To prevent relapse, it is reasonable to continue this dose for an additional 24 hours and then taper to 50 mg every 6 to 8 hours for the next 2 days. Clinical trials have shown that oral naproxen, fenoprofen, ibuprofen, sulindac, piroxicam, and ketoprofen, as well as intramuscular ketorolac, are also effective. In fact, all members of this family of drugs can be highly effective in the treatment of acute gouty arthritis, including the cyclooxygenase-2 (COX-2) selective agents.[186]

### Corticosteroids

Intra-articular glucocorticoids are useful in the treatment of acute gout limited to a single joint or bursa.[172,187] Oral, intramuscular, or intravenous glucocorticoids can also provide relief, but these agents are usually reserved for patients who are intolerant of colchicine or NSAIDs or have medical conditions such as peptic ulcer disease or renal disease that contraindicate their use. Doses of glucocorticoids have been systematically studied, and generally, high doses (prednisone, 0.5 mg/kg, or at least 20 to 60 mg/day) are necessary. Lower doses may not be effective, as evidenced by gout flares occurring in organ transplant patients who are taking prednisone at maintenance doses of 7.5 to 15 mg a day.[188] Anecdotally, rebound attacks have been reported as steroids are withdrawn.

### Adrenocorticotropic Hormone

Single injections of intramuscular ACTH gel (25 to 80 IU) can terminate an acute gout attack.[189] More often, however, repeated administration is required every 24 to 72 hours. This treatment is effective post-operatively and may be more effective than glucocorticoids, possibly because of the mechanism of action. In addition to stimulating the adrenal cortex to produce corticosteroids, ACTH interferes with the acute inflammatory response through activation of melanocortin receptor-3.[190] Unfortunately, ACTH preparations, when they are available at all, have become prohibitively expensive. The branded ACTH gel initially approved by the FDA for a variety of indications in 1952, was reapproved in 2010 to treat infantile spasms, exacerbations of multiple sclerosis, and 17 other indications. Ironically, acute gout was not one of those indications.

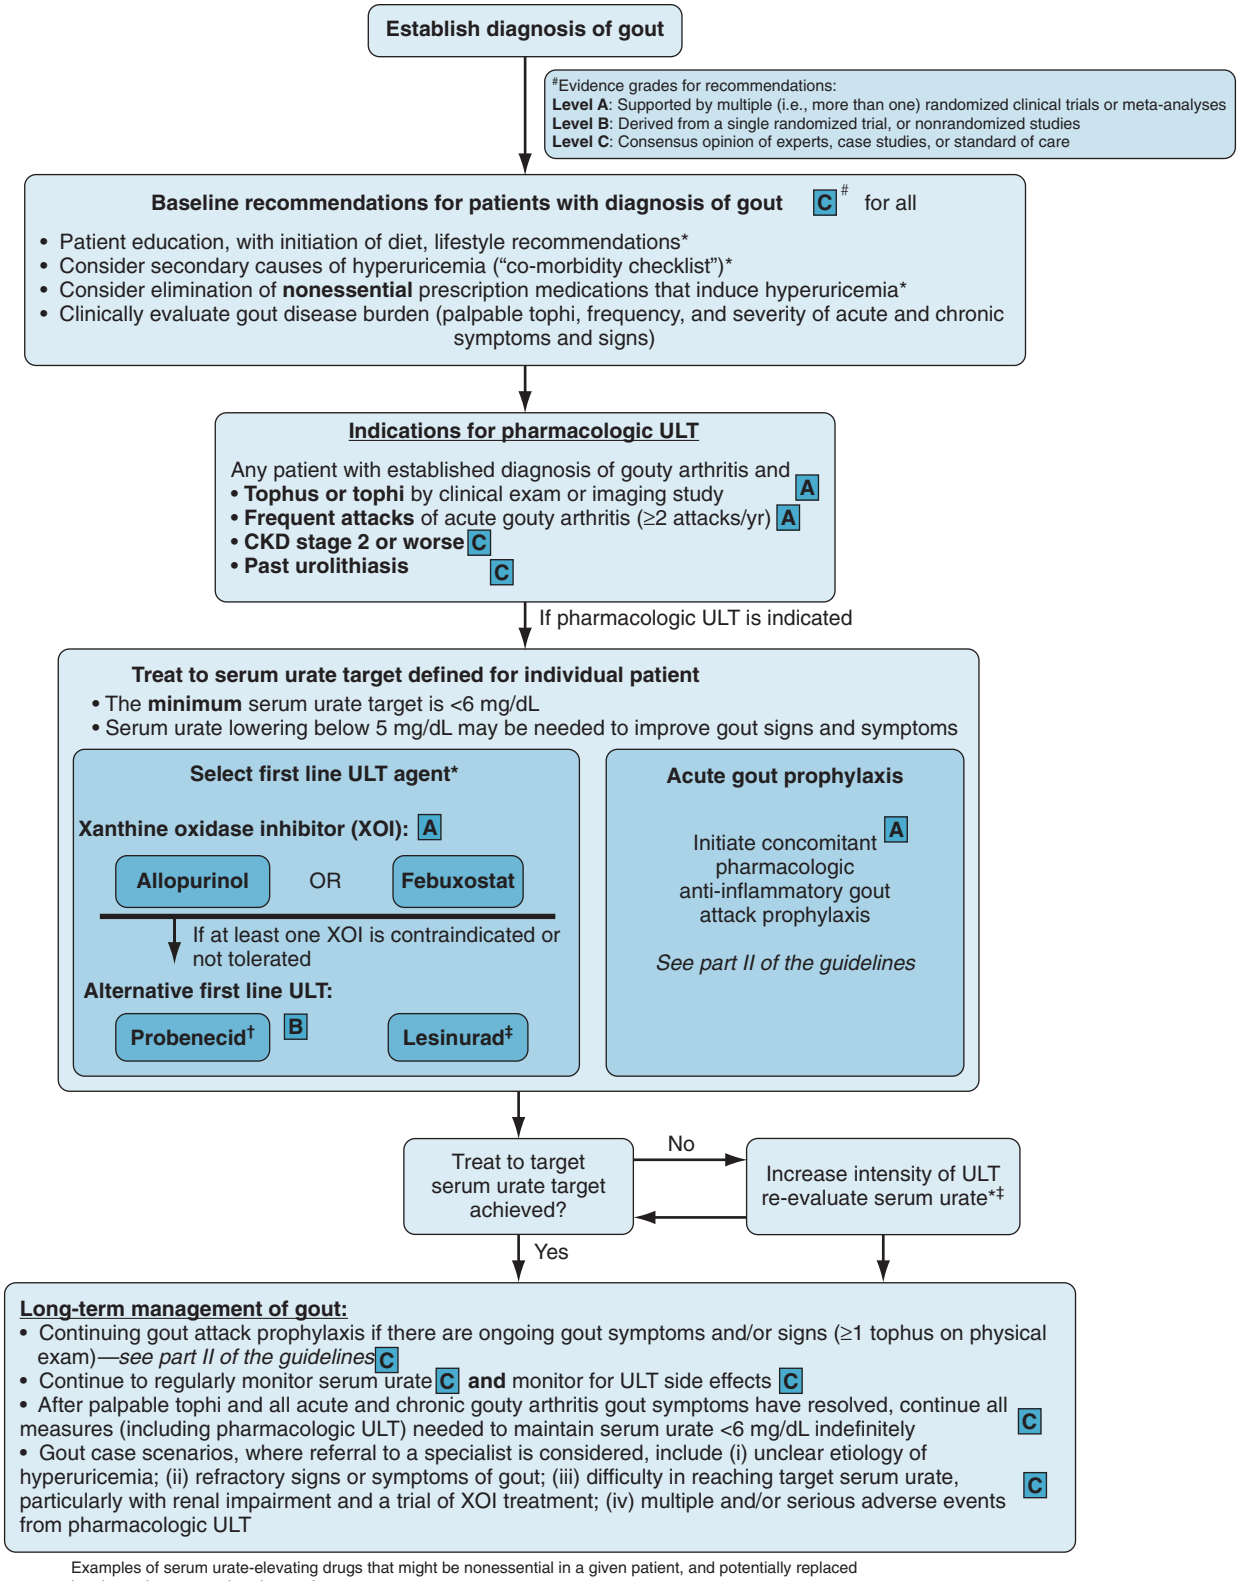
### IL-1 Inhibition

In response to the recognition of the critical role that IL-1β plays in the initiation of gout attacks, trials of biologic inhibitors of IL-1β for both the treatment and prophylaxis of acute gout have been undertaken with promising results.[167-171] Although approved for the treatment of TNF receptor–associated periodic fever syndromes, these expensive agents have not yet been approved in the United States for gout. Concerns about cost and adverse effects in elderly individuals have been raised by the FDA. However, in early 2013, the European Commission approved canakinumab for patients with gout who experience frequent gout attacks (at least three attacks in the past 12 months) and in whom

NSAIDs and colchicine are contraindicated, are not tolerated, or do not provide an adequate response, and in whom corticosteroids are inappropriate. Canakinumab is a humanized monoclonal antibody directed against IL-1β and is administered as a single, subcutaneous injection of 150 mg.

### Prophylaxis

Approximately 50% of patients with gout will experience acute flares after initiation of urate-lowering therapy. The practice of giving small daily doses of colchicine as prophylaxis to prevent acute attacks is up to 85% effective in preventing those attacks.[191] Colchicine, 0.6 mg one to three times a day, is generally well tolerated, although the drug may produce a reversible axonal neuromyopathy.[192] This complication causes proximal muscle weakness with or without painful paresthesia and elevated serum levels of creatine phosphokinase, which is most often seen in patients with hypertension, renal dysfunction, or liver disease who are also taking diuretics. Rhabdomyolysis may also occur in these settings and is more common in people who are also taking a statin (hydroxymethylglutaryl–coenzyme A [HMG-CoA] reductase inhibitor) or cyclosporine.[193] Dosing of colchicine should be decreased for people with moderate to severe renal insufficiency.



In patients who are unable to tolerate even one colchicine tablet per day, indomethacin or another NSAID has been used prophylactically at low doses (e.g., indomethacin, 25 mg twice a day, or naproxen, 250 mg a day or twice a day) with some success.[194] Some patients may require combination therapy of colchicine and NSAIDs. Peptic ulcer disease prophylaxis should be considered in at-risk patients. Maintenance doses of colchicine or an NSAID may make the difference between frequent incapacitation and uninterrupted daily activities. Prophylaxis is usually continued until the serum urate value has been maintained well within the normal range and no acute attacks have occurred for 3 to 6 months. The 2012 ACR Guidelines for Management of Gout recommend continuing prophylaxis for 6 months, or 3 months after achieving target serum urate for patients without tophi, or 6 months after achieving target serum urate with resolution of tophi.[58] It is important to warn patients that colchicine and/or NSAID discontinuation may be followed by an exacerbation of acute gouty arthritis and to advise them about what to do should an attack occur. Finally, prophylactic treatment is not recommended unless the clinician also uses urate-lowering agents. Prophylactic colchicine may block the acute inflammatory response but does not alter the deposition of crystals in tissues. When deposition continues without the warning signs of recurrent bouts of acute arthritis, tophi and destruction of cartilage and bone can occur without notice.

## Control of Hyperuricemia

Elimination of hyperuricemia with urate-lowering therapy can prevent and reverse urate deposition and perhaps improve renal function.[135,136] Today, opinion differs with regard to when in the course of gout the clinician should start urate-lowering therapy, although all persons agree that it should be initiated before the chronic inflammatory response that surrounds tophi has caused cartilage and bone erosion. Some physicians regard the first gout attack as a late event in a disorder marked by years of antecedent silent deposition of urate crystals in cartilage and other connective tissue. Other physicians believe that because tophi and symptomatic chronic gouty arthritis develop in only a minority of cases and ordinarily develop slowly after many years of recurrent acute attacks, unnecessary or premature medication can be avoided without demonstrable penalty. In practice, it is rare to have a patient who never experiences a second attack. The probability of such a benign course is greatest in patients who have only minimally elevated serum urate concentrations and normal 24-hour urinary uric acid values. Arguably, a case can be made for initiating antihyperuricemia therapy after the second attack in most patients.[194] The 2012 ACR Guidelines recommend initiation of urate-lowering therapy in patients with an established diagnosis of gouty arthritis AND tophaceous deposits by examination or imaging, frequent attacks defined as at least two per year, chronic kidney disease that is stage 2 or worse, or a history of urolithiasis (Figure 95-14).[58] Obviously, general recommendations of this type must be tempered by the clinician's best judgment. For example, a patient with gout who has experienced a single significant attack each year for the past several years should be receiving urate-lowering therapy.[195]

Urate-lowering therapy provides a definitive method for controlling hyperuricemia. Although it is important to treat and prevent acute attacks of gouty arthritis with anti-inflammatory agents, it is the long-term control of hyperuricemia that ultimately modifies the manifestations of the gouty diathesis. Once started, treatment with specific urate-lowering agents is lifelong, and the dose must be sufficient to maintain the serum urate level below 6.8 mg/dL—preferably between 5 and 6 mg/dL. Lowering the serum urate level from 11 mg/dL to 7.5 mg/dL may seem encouraging, but this change does not reverse the process; it merely slows the rate at which crystals continue to deposit. Generally, the lower the serum urate level achieved during urate-lowering therapy, the faster the reduction in tophaceous deposits.[196] The 5 to 6 mg/dL target is recommended because it is far enough below the saturation level of 6.8 mg/dL that it provides some margin for fluctuations in serum levels and avoids excessive exposure to the medication, which might increase the chance of toxicity. Particularly in cases in which extensive tophi are present on physical examination, a target serum urate of less than 4.0 mg/dL may be appropriate to achieve a timely reduction in the total body urate burden. Reduction to target levels may be achieved pharmacologically through the use of xanthine oxidase inhibitors, uricosuric agents, or uricases. Xanthine oxidase, the enzyme that catalyzes the oxidation of hypoxanthine to xanthine and xanthine to uric acid, is inhibited by allopurinol, oxypurinol, and febuxostat. Probenecid, lesinurad (recently approved by the FDA; see subsequent text), sulfinpyrazone, and benzbromarone are uricosuric agents that reduce serum urate concentrations by enhancing the renal excretion of uric acid. Rasburicase and pegloticase enzymatically convert urate to allantoin, which is much more soluble and readily excreted in the urine. These urate-lowering drugs do not have anti-inflammatory properties.

For patients with gout who excrete less than 800 mg of uric acid per day and have normal renal function, reduction

Examples of serum urate-elevating drugs that might be nonessential in a given patient, and potentially replaced by alternative agents that do not elevate serum urate:
- Niacin for management of hyperlipidemia
- Thiazide and loop diuretics for hypertension. However, in discussion, and without a specific vote, the TFP recognized the value of thiazide treatment in many patients with hypertension, and cautioned against imprudent cessation of thiazide treatment to lessen hyperuricemia at the cost of worsened control of blood pressure in difficult to control hypertension.
- Calcineurin inhibition with cyclosporine or tacrolimus, if it is not essential for immune suppression

*See original referenced article for details.
†Probenecid is not recommended as a first line or alternative first-line ULT agent if the CrCl is <50 (Evidence C)
‡The recently FDA-approved combination of lesinurad and an XOI is now an option, 3 years after the ACR guidelines were published

**Figure 95-14** Baseline recommendations and overall strategic plan for patients with gout. Note that this is an evolving field, and this does not include uricase or URAT1 transporter inhibitors. Part 1: systematic non-pharmacologic and pharmacologic therapeutic approaches to hyperuricemia.* Arthritis Care Res *64:1431, 2012.)*

of the serum urate concentration can be achieved equally well with a xanthine oxidase inhibitor or a uricosuric drug. These agents are equally effective in preventing the deterioration of renal function in patients with primary gout.[197] In most cases, allopurinol is the drug of choice because it can be used with fewer restrictions compared with uricosuric agents.

In general, the ideal candidate for uricosuric agents is a patient with gout who is younger than 60 years and has normal renal function (creatinine clearance >80 mL/min), uric acid excretion of less than 800 mg per 24 hours on a general diet, and no history of renal calculi. When uricosuric agents are prescribed, patients should be counseled to avoid salicylate use at doses greater than 81 mg/day.[198]

In certain situations, an inhibitor of xanthine oxidase is clearly the drug of choice in a patient with gout. People with gout who excrete more than 1000 mg per 24 hours of uric acid in their urine or who have a history of renal calculi of any type should be treated with a xanthine oxidase inhibitor (Table 95-6). The incidence of renal calculi is about 35% in patients with primary gout who excrete more than 700 mg/day of uric acid.[41] The risk for uric acid stones is also greater upon initiation of uricosuric therapy. In addition, patients with tophi generally should take a xanthine oxidase inhibitor to decrease the load of urate that must be handled by the kidney. Patients with gout and mild renal insufficiency can be given either type of agent, but probenecid and sulfinpyrazone would not be expected to work when the glomerular filtration rate is less than 50 mL/min. Allopurinol is effective in the presence of renal insufficiency, but doses may need to be decreased in that situation. Febuxostat needs no adjustment in mild to moderate renal insufficiency. A final indication for a xanthine oxidase inhibitor is the failure of uricosuric agents to produce a serum urate concentration lower than 6 mg/dL or patient intolerance of the uricosuric agent. A xanthine oxidase inhibitor and a uricosuric drug may be used in combination in a patient with tophaceous gout for whom it is not possible to reduce the serum urate below 6 mg/dL with a single agent. The uricosuric agent lesinurad, a selective URAT1 inhibitor, was approved by the FDA in December of 2015 for the treatment of hyperuricemia in patients with gout who have failed to reach a target serum uric acid level of less than 6.0 mg/dL while taking allopurinol or febuxostat. In clinical trials, the combination of lesinurad 400 or 600 mg per day in combination with allopurinol 200 to 600 mg per day resulted in 74% to 79% of patients achieving serum urate levels less than 6.0 mg/dL.[198a] The combination of lesinurad 400 or 600 mg per day with feuxostat 40 or 80 mg per day resulted in 100% achieving a serum uric acid less than 5.0 mg/dL.[198b] In most settings, however, if allopurinol or febuxostat does not cause the serum urate to drop below 6 mg/dL, it is the result of insufficient dosing or poor patient compliance. The 2012 ACR Guidelines include specific recommendations regarding the use of allopurinol and uricosurics in patients with gout.[58] The FDA and EMA approved pegloticase, a mammalian uricase covalently attached to poly(ethylene glycol) with reduced immunogenicity for the treatment of difficult, tophaceous gout in 2010 and 2013, respectively.[198c] Although pegloticase offers the possibility of a rapid reduction of tophi (Figure 95-9), this drug still has a high rate of infusion reactions, including anaphylaxis, in up to 7% of patients.[198d] The incidence of treatment-induced gout flares is also very high. Therefore pegloticase is only appropriate for those patients with tophaceous gout with a large excess of total body urate and persisting gout attacks, or with damaging arthropathy, who are intolerant of or who have failed conventional treatment.[167] For a detailed discussion of the use of urate-lowering agents, see Chapter 66 of this textbook.

## COMPLIANCE WITH TREATMENT

Because the disease processes involved in gout are so well understood, the diagnosis generally can be readily established. Once gout is diagnosed, the available therapies are so effective that it should be an easily managed disease. However, too many patients, including those who are accurately diagnosed, do not do well. Failure of urate-lowering therapy to attain the target urate level is usually due to improper prescribing or poor compliance.[199] The most commonly prescribed dose of allopurinol (300 mg) is effective in getting serum urate levels to less than 6.0 mg/dL in only about 40% of patients. Furthermore, a review of 16 clinical studies revealed a compliance rate for taking gout medications of only 10% to 46%.[199] Compliance is often a problem when treating chronic asymptomatic conditions, and associated alcoholism can be a factor. Perhaps more important is the fact that patients may need to take up to three different medications on three different schedules to control their symptoms and treat the disease.

It is believed that if patients understand why they are taking medications, they are more likely to be compliant. Toward this end, an analogy has been developed that helps some patients become more compliant.[200] In this analogy, urate crystals are compared with matches. The patient is told that "when the match strikes," it causes a gout attack. To "put out the fire," the patient takes an NSAID or colchicine. Although this resolves the attack, "the matches are still there." To eliminate future attacks, the patient is given prophylactic colchicine, "which makes the matches damp and harder to strike," and allopurinol (or a uricosuric agent), "which actually removes the matches from the body."

## MANAGEMENT OF GOUT AFTER ORGAN TRANSPLANTATION

The management of patients with gout after organ transplantation requires careful consideration. The use of glucocorticoids, azathioprine, or cyclosporine and the precarious status of renal function in many patients poses complex problems. Colchicine and NSAIDs may be inappropriate for the management of acute gouty arthritis in this setting because of their potential toxicities. Intra-articular glucocorticoid injections may be most helpful, and one may be forced to rely more heavily on pain medications in this setting. Prophylactic colchicine can be used in patients with normal renal function, but treatment must be monitored closely. The combination of colchicine and cyclosporine has induced rhabdomyolysis.[193]

When considering chronic therapy, it is helpful to lower the doses of cyclosporine and eliminate the use of diuretics, if possible. Uricosuric agents can be used safely, but their usefulness declines if renal function is poor. Allopurinol can be used in patients with abnormal renal function, but the dose may need to be reduced. Febuxostat may be safer in this setting but has not been studied. However, both allopurinol and febuxostat may have severe interactions with azathioprine. Azathioprine is metabolized by xanthine oxidase, and because these drugs inhibit that enzyme, the breakdown of azathioprine is slowed, increasing the effective dose. If care is not taken, significant bone marrow toxicity can result. Thiopurine *S*-methyltransferase studies should be obtained before starting azathioprine. When azathioprine and allopurinol are used together, they can be started at 25 and 50 mg/day, respectively.[201] Revised dosing for febuxostat in such a situation has not been determined. Complete blood cell counts and serum urate level concentrations are then monitored weekly when using allopurinol, and the dose is adjusted to bring the serum urate concentration down to less than 6 mg/dL. As an alternative to azathioprine, mycophenolate mofetil has been used effectively with allopurinol in some transplant patients.[202]

Uricase has been used to drastically lower serum urate levels and shrink tophi in a small number of patients with gout after cardiac transplantation.[203] This treatment has been associated with significant allergic reactions, including anaphylaxis, bronchospasm, and hemolytic anemia. The newer preparations of uricase such as pegloticase may avoid those complications and prove more effective.

## ANCILLARY FACTORS

In addition to anti-inflammatory agents, colchicine prophylaxis, and urate-lowering therapy, other factors may be decisive in determining whether the following symptoms develop: recurrent attacks, chronic gouty arthritis, kidney stones, or nephropathy. Today, dietary purine restriction solely to control serum urate levels is rarely advised. A totally purine-free diet reduces the urinary excretion of uric acid by only 200 to 400 mg/day and lowers the mean serum urate value by about 1 mg/dL. In addition, the urate-lowering agents available today are so effective that this type of dietary manipulation is rarely necessary. Nevertheless, beneficial results have been reported with a diet of moderate calorie and carbohydrate restriction and a proportionally increased intake of protein and unsaturated fat.[204] Some subjects with gout are susceptible to acute attacks after the consumption of alcoholic beverages or rich foods. Others describe idiosyncratic responses such as acute gout after eating a particular food, but such relationships are rare and questionable. A diet designed to avoid indiscretions known to precipitate acute gouty attacks in a particular individual is recommended.

In addition, diet is important with regard to other medical problems.[205] Many patients with gout are overweight, and restoration of ideal body weight through regulated calorie restriction is recommended. In addition, at least 75% of patients with primary gout have hypertriglyceridemia. The initial step in managing hypertriglyceridemia is reduction to an ideal body weight and elimination of alcohol ingestion. Fenofibrate is the only drug in its class that is uricosuric.[165] Therefore it may be a useful agent in managing lipid abnormalities.

Many patients with gout consume liberal amounts of alcohol. Acute excesses can lead to exacerbations of hyperuricemia as a result of temporary hyperlactacidemia, and chronic ingestion of alcohol may stimulate increased purine production.[123] The added purine load resulting from regular ingestion of beer may also be a contributing factor. Patients should be warned about the deleterious effects of excessive alcohol intake. Compliance with medication is also much worse among patients who consume alcohol. The 2012 ACR Guidelines include specific recommendations regarding lifestyle measures for patients with gout[58] (Figure 95-15).

About one-third of subjects with gout are hypertensive. The complications of hypertension are potentially more serious than those of hyperuricemia, and the clinician should not hesitate to use whatever drugs are necessary to control the hypertension. Many hypertensive patients with gout require a thiazide diuretic. If this medication is necessary to control hypertension, it should be used, with the recognition that the dosage of concomitant urate lowering therapy may need to be adjusted to maintain appropriate control of serum urate levels. Losartan is the only antihypertensive medication that has uricosuric properties.[166]

## CONCLUSION

Gout is an ancient malady. Although it is one of the best understood diseases, its incidence continues to rise. An epidemic of obesity and other factors have driven this increase. In addition, persistent misconceptions about the appropriate use of gout medications, poor patient compliance, and difficult comorbidities as patients live longer have led to suboptimal management of the disease. The diagnosis of gout should be substantiated by identification of intra-articular monosodium urate crystals whenever possible, guidelines for starting urate-lowering treatment should be followed, prophylaxis against flares early in such treatment should be given for at least 6 months, a serum urate of 6 mg/dL or lower should be targeted, and long-term patient compliance should be reinforced.

Major new insights into the pathogenesis of hyperuricemia and gout have occurred during the past few years, including fine details of the handling of uric acid in the

| • Alcohol overuse (defined as more than two servings per day for a male and one serving per day for a female) in all gout patients B<br>• Any alcohol use in gout during periods of frequent gout attacks, or advanced gout under poor control C | • Alcohol (particularly beer, but also wine and spirits) in all gout patients B | |

*Without a specific task force panel (TFP) vote, adherence to diets for cardiac health and control of comorbidities, such as obesity, metabolic syndrome, diabetes, hyperlipidemia, and hypertension, was stressed for gout patients, as appropriate.
[†]The TFP recommendation to "encourage" intake was not intended to advocate excesses in consumption of specific dietary items. There was a lack of TFP voting consensus on cherries and cherry products, ascorbate (in supplements or foods), nuts, and legumes. The TFP did not specifically vote on the question of limits on consumption of purine-rich vegetables and legumes.

renal proximal tubule and the cellular inflammatory response to monosodium urate crystals. In addition, newer therapeutic agents are available, and several others are entering the market, including IL-1 inhibitors for the treatment and prophylaxis of acute gout. The excitement generated by these changes offers an ideal opportunity to re-educate our patients and ourselves so as to improve outcomes in this highly treatable disease. Better management of gout with old and newly available drugs, as well as a concerted effort on the part of society to change negative lifestyle choices, will, it is hoped, have a positive effect on gout incidence and outcome in the years to come.

CHAPTER 96

# Calcium Crystal Disease:
## Calcium Pyrophosphate Dihydrate and Basic Calcium Phosphate

Robert Terkeltaub

**KEY POINTS**

- Dysregulated inorganic pyrophosphate ($PP_i$) metabolism, intimately associated with altered chondrocyte differentiation and extra-cellular matrix composition, is central in the pathogenesis of calcium pyrophosphate (CPP) dihydrate crystal deposition disease (CPPD).
- Autosomal dominant familial CPPD has been linked in multiple kindreds to certain mutations in *ANKH,* a gene encoding a $PP_i$ transporter.
- NLRP3 (cryopyrin) inflammasome activation and consequent caspase-1 activation and interleukin (IL)-1β processing and secretion drive inflammatory responses to CPP and BCP crystals.
- Degenerative arthropathy caused by CPPD often involves joints uncommonly affected by primary osteoarthritis, such as the metacarpophalangeal, wrist, and elbow joints.
- Diagnosis of CPPD in patients younger than 55 years, particularly if CPP crystal deposition is polyarticular, should prompt the differential diagnostic consideration of a primary metabolic or familial disorder. Such disorders also can first appear with clinical manifestations of CPPD in patients older than 55 years.
- High-resolution ultrasound is helpful in diagnosis of CPPD, partly because radiographic chondrocalcinosis is not detectable in all joints affected by the disease.
- CPP and basic calcium phosphate (BCP) crystal deposition in articular cartilage are very common in primary osteoarthritis (OA), particularly with advanced disease.
- CPP and BCP crystals can promote symptomatic flares of primary OA, but their net role in promoting OA progression is not well-characterized.
- BCP crystals (unlike monosodium urate and CPP crystals) are not birefringence, and specialized methods are required to identify BCP crystals in specimens from the joint.

The proposed diagnostic criteria for calcium pyrophosphate dihydrate (CPPD) are shown in Table 96-1, as adapted by the author from the European League against Rheumatism (EULAR) criteria[1] and the original criteria proposed in the past by Daniel J. McCarty and colleagues. The diagnosis is based on detection of CPP crystals by one or more methods. These include not only standard clinically applied radiography but also high-resolution ultrasound to detect hyaline articular cartilage or fibrocartilage calcifications characteristic of CPP crystal deposition (termed *chondrocalcinosis*). However, identification of CPP crystals via compensated polarized light microscopic analysis of synovial fluid in the absence of joint infection or other cause of arthritis is the gold standard for diagnosis of CPPD, particularly for acute CPP crystal-associated arthritis (classically termed *pseudogout*). Detection of typical CPP crystals in tissue sections also can be accomplished whether specimens are fixed in formaldehyde or ethanol, unlike the case for monosodium urate crystals (which dissolve in formaldehyde). Specialized crystal analytic approaches including radiography energy spectroscopy and powder diffraction analysis or atomic force microscopy can be used to distinguish CPP crystal deposition from basic calcium phosphate (BCP) crystal deposition. In assessing the form of crystals deposited in calcifications, determination of the calcium/phosphate ratios and the spacing of radiography powder diffraction lines provide the most specific information.

Consensus clinical diagnostic criteria for articular BCP crystal deposition disorders are not in place. Importantly, BCP crystals (unlike monosodium urate and CPP) do not demonstrate global birefringence, although the aggregated particles of basic calcium phosphate crystals demonstrate edge birefringence. Hence, diagnosis is predicated on detection of (1) radiographic detection of calcifications characteristic of BCP crystals, or (2) BCP crystals confirmed by transmission electron microscopy or specialized crystal analytic approaches (including those mentioned earlier for CPP crystals and discussed below). In some clinical pathology laboratories, the calcium-binding dye alizarin red S is used to stain synovial fluid samples, because BCP crystals stain strongly for alizarin red S, whereas CPP crystals stain weakly with this dye.

## EPIDEMIOLOGY

**KEY POINTS**

- True prevalence of both CPPD and pathologic articular BCP crystal deposition is not known because of limits of radiographic detection and lack of large pathology studies of joint tissues in populations at large.
- The prevalence of CPPD, including asymptomatic disease, increases with aging.
- Idiopathic/sporadic CPPD is rare in patients younger than 55 years, particularly in the absence of a history of joint trauma or knee meniscectomy.
- The epidemiology of CPPD is not uniform among populations.

**CPPD prevalence might be increasing in developed countries, mediated by both increased longevity and iatrogenic factors in such countries that promote hypomagnesemia.**

**The knee might be spared of radiographically detected chondrocalcinosis in many patients with CPPD, and should not be the sole joint screened.**

In the past, studies of the prevalence of both CPPD[2-5] and various forms of articular BCP crystal deposition disease have been predominantly based on characteristic plain radiographic features of the disease in limited numbers of joints. This is an incompletely sensitive and specific approach.[2] Other studies have been based on results of synovial fluid analyses, but definitive studies based on pathologic findings on examination of articular cartilages, or imaging approaches superior to plain radiography, have not been done. As such, the true prevalence of both CPPD and pathologic articular BCP crystal deposition is not known. However, we do know that CPPD, including asymptomatic disease, increases progressively in prevalence with aging.[2-5] Idiopathic/sporadic CPPD is rare in patients younger than 55 years, particularly in the absence of a history of joint trauma or knee meniscectomy.[6,7]

In a large U.K. community study, the age-, sex-, and knee pain–adjusted prevalence of knee CPPD was 4.5% for patients older than 40 years.[3] In some studies, women have appeared somewhat more commonly affected by CPPD than men[1]; however, in the U.K. study, there was no sex predisposition, although a strong association between primary osteoarthritis (OA) and chondrocalcinosis was confirmed.[3] This appeared to be linked more to the presence of osteophytes rather than joint space narrowing with OA. Most but not all elderly patients with CPPD of the knee also have detectable chondrocalcinosis in other joints; this may not be the case for hip CPPD, at least in association with hip OA.[8,9] Knee meniscal fibrocartilage calcification alone has been detected in approximately 15% of those aged 80 to 89 years and in approximately 30% older than 89 years.[7] Studies based on radiographs have estimated a higher prevalence of CPPD when the hands, wrists, pelvis, and knees have been surveyed.[7] Knees are spared of radiographically detected chondrocalcinosis in many with CPPD,[9] and should not be the sole joints screened for research or clinical studies.

CPPD is not uniform in epidemiology among populations. For example, in a random sample of Beijing residents older than 60 years, radiographic chondrocalcinosis was compared with whites in the American Framingham OA Study.[11] The Chinese had a much lower prevalence of knee chondrocalcinosis, and wrist chondrocalcinosis was particularly rare in Chinese elderly.[11] These findings were unexpected because there is an excess of knee OA in the Beijing population, and CPPD and OA are quite commonly associated in the knee joint. Analyses of patients of Chinese extraction in the United States would be informative.

CPPD prevalence may be increasing in developed countries, mediated both by increased longevity and iatrogenic factors in such countries that promote hypomagnesemia.[10] Such iatrogenic factors include loop diuretics,[3] proton pump inhibitors, calcineurin inhibitors (cyclosporine, tacrolimus), and post-surgical short bowel syndrome.[7,10] Other risk factors for CPPD may include low cortical bone density, for unclear reasons.[7] Knee CPPD risk appears to be increased by knee malalignment, predominantly varus, in early life.[6]

Novel reported associations of CPPD include low BMI and low cortical bone mineral density.[11a] The risk of acute episodic CPP crystal arthritis is increased in those on loop diuretics, and with hyperparathyroidism and end stage renal disease.[11a]

**Table 96-1** Proposed Diagnostic Criteria for CPPD

| | |
|---|---|
| **Criteria** | |
| I. | Demonstration of CPP crystals, obtained by biopsy or aspirated synovial fluid, by definitive means (such as characteristic radiography diffraction powder pattern) |
| II. A. | Identification of monoclinic or triclinic crystals showing a weak positive birefringence (or no birefringence) by compensated polarized light microscopy |
| B. | Presence of typical calcifications on radiographs (as discussed in text): heavy punctate and linear calcifications in fibrocartilages, articular (hyaline) cartilages, and joint capsules, especially if bilaterally symmetric |

CPPD, Calcium pyrophosphate dihydrate crystal deposition disease.
Modified from McCarty DJ: Crystals and arthritis. *Dis Month* 6:255, 1994.

## GENETICS

**KEY POINTS**

**The vast majority of CPPD is idiopathic/sporadic, but early-onset familial disease also occurs.**

**Linkage of familial CPPD to the gene *ANKH* on chromosome 5p (which encodes a transmembrane protein with functions including $PP_i$ transport) is well established.**

The vast majority of CPPD is idiopathic/sporadic, but early-onset (defined as onset before 55 years) familial disease also occurs.[12,13] Two major chromosomal linkages, 8q and 5p have been identified in studies of familial CPPD. Linkage with chromosome 8q of both early-onset OA and chondrocalcinosis appears much less common than chromosome 5p-linked chondrocalcinosis, which is linked to *ANKH* on chromosome 5p (which encodes a transmembrane protein with $PP_i$ transport and other apparent functions).[12-17] *ANKH* functions and clinical phenotypes linked to specific mutations are discussed later, for dysregulated $PP_i$ metabolism in pathologic cartilage calcification.

Familial CPPD is heterogeneous. For one example, prominent CPP and hydroxyapatite (HA) crystal deposits and cartilage and periarticular calcifications in association

with OA were described in a kindred not yet linked to a specific chromosomal locus.[18] A syndrome of spondyloepiphyseal dysplasia tarda, brachydactyly, precocious OA, and intra-articular calcifications with CPP and/or HA crystals, as well as periarticular calcifications, was linked to mutation of the procollagen type II gene in indigenous natives of the Chiloe Island region of Chile, who have high prevalence of familial CPPD. Families affected with diffuse idiopathic skeletal hyperostosis (DISH) and/or chondrocalcinosis have been identified in the Azores Islands, possibly reflecting an unidentified, shared pathogenic mechanism.[19]

## ETIOLOGY AND PATHOGENESIS

### KEY POINTS

**The loose avascular connective tissue matrices of articular hyaline cartilage, fibrocartilaginous menisci, and certain ligaments and tendons are particularly susceptible to pathologic calcification.**

**Joint cartilage pathologic calcification reflects complex interplay between organic and inorganic biochemistry of $P_i$ and $PP_i$ metabolism and transport, dysregulated chondrocyte growth factor responsiveness and differentiation, and other factors.**

**In most patients, CPPD is a systemic articular and soft-tissue metabolic disorder, likely driven by dysregulated ATP and $PP_i$ metabolism resulting from impaired mitochondrial function, linked with joint tissue aging and OA.**

**Environmental factors promoting CPPD likely include dietary mineral content and regulators of body stores of iron, calcium, phosphate, and magnesium, with downstream effects including modulation of parathyroid hormone levels and the catalytic activity of enzymes involved in $PP_i$ metabolism.**

The loose avascular connective tissue matrices of articular hyaline cartilage, fibrocartilaginous menisci, and of certain ligaments and tendons are particularly susceptible to calcification. Calcium-containing crystals deposited in the pericellular matrix of cartilage are often in the form of CPPD (chemical formula, $Ca_2P_2O_7{\cdot}H_2O$; calcium-to-phosphate ratio of 1). Crystals of BCP including partially carbonate-substituted HA ($Ca_5[PO_4]_3OH{\cdot}2H_2O$; calcium-to-phosphate ratio of 1.67) also may be deposited pathologically in articular cartilage, particularly in OA. Importantly, physiologic non-inflammatory deposition of HA is essential because HA is the principal mineral phase laid down in growth cartilage and in bone.

Inflammatory conditions also may result from deposition of HA, as well as the closely related BCP crystals, octacalcium phosphate (OCP) ($Ca_8H_2[PO_4]_6{\cdot}5H_2O$; calcium-to-phosphate ratio, 1.33) and tricalcium phosphate or "whitlockite" ($Ca_3[PO_4]_2$; calcium-to-phosphate ratio, 1.5) in periarticular structures such as the rotator cuff (calcific tendinitis) and subacromial bursa of the shoulder (see Chapter 46). CPP and BCP crystal deposition, reviewed here, are by far the most prevalent arthropathies associated with calcium-containing crystals. Articular calcium oxalate crystal deposition is less common.

Articular cartilage, unlike growth plate cartilage, is specialized to avoid the process of matrix calcification. However, the matrix of articular hyaline cartilage, like that of fibrocartilaginous menisci, lends itself well to pathologic calcification, particularly in association with certain changes in extra-cellular matrix composition and hydration in aging and OA. Joint cartilage calcification reflects a complex interplay between organic and inorganic biochemistry, ion transport, aging, genetics, inflammation, oxidative stress, and dysregulated chondrocyte growth factor responsiveness and differentiation. Pathologic cartilage calcification can reflect deficiencies of certain physiologic calcification inhibitors or upregulation of mediators that actively drive certain patterns of tissue injury, culminating in calcification within degenerating cartilage.[20]

Alteration of the concentrations of calcium, inorganic phosphate ($P_i$), $PP_i$, and the solubility products of these ions are clearly at work in promoting CPP and BCP crystal formation.[20] The levels of ambient $Mg^{2+}$ and the composition of the chondrocyte extra-cellular matrix influence the dynamics of CPP crystal formation. $Mg^{2+}$ helps to determine whether predominantly monoclinic or less inflammatory triclinic CPP crystals are predominantly formed.

Specific extra-cellular matrix effects for CPP and BCP crystals, characterized partly in experimental gel systems, include promotion of CPP crystal formation by adenosine triphosphate (ATP) and corticosteroids in conjunction with matrix type I collagen and osteopontin,[21] whereas type II collagen and intact proteoglycans appear to suppress ATP-driven CPP crystal formation in vitro. Experimental systems to analyze CPP and BCP crystal deposition have commonly used isolated matrix vesicle cell fragments from chondrocytes that are enriched in procalcifying constituents and provide a nidus for initiation of calcification, specifically with BCP crystals. Matrix vesicles are important in cartilage growth plate calcification, but it is not yet clear whether CPP and BCP crystal formation in articular cartilages is driven more by matrix vesicle–mediated effects or nucleation of crystals in association with changes in extra-cellular matrix constituents, or both pathways. CPP crystals are too large (micron size) to form within matrix vesicles, but loci of pericellular concentration of $PP_i$ may be necessary to drive CPP crystal formation at low micromolar $PP_i$ concentrations developing in cartilages with CPPD.

Besides physical effects of $Ca^{2+}$, $P_i$, and $PP_i$ on crystal nucleation and propagation, these same solutes exert a variety of mineralization-regulating effects on gene expression, differentiation, and viability in chondrocytes, mediated partly by calcium-sensing receptors and sodium-dependent inorganic phosphate cotransport in chondrocytes.[22-25] Noxious effects of excess $PP_i$ on chondrocytes, including induction of matrix metalloproteinase-13 (MMP-13) expression[26] and promotion of apoptosis[27]; noxious effects of extra-cellular ionized $Ca^{2+}$ on chondrocytes include potentiation of the ability of transforming growth factor (TGF)-β to promote $PP_i$ release.[28]

Primary idiopathic CPPD (i.e., without a precipitating cause, such as joint trauma, or a secondary metabolic disorder) is likely promoted by a systemic tendency to deposit calcium containing crystals and involves tissues beyond joint cartilages, including tendons, and possibly also the arterial wall.[11a] The systemically disordered articular and soft-tissue metabolic basis of most CPPD is reinforced by

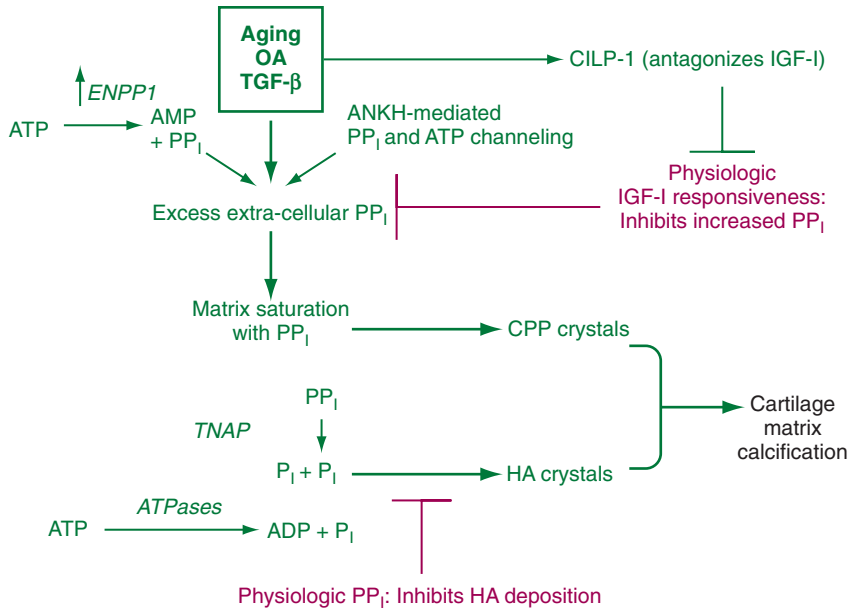

**Figure 96-1** Proposed inorganic pyrophosphate ($PP_i$)-dependent mechanisms stimulating calcium pyrophosphate (CPP) dihydrate and hydroxyapatite (HA) crystal deposition in aging and osteoarthritis (OA). Roles of adenosine triphosphate (ATP) and $PP_i$ metabolism and inorganic phosphate ($P_i$) generation in pathologic cartilage calcification. This model accounts for the association of extra-cellular $PP_i$ excess with both CPP and basic calcium phosphate (HA) crystal deposition in OA and chondrocalcinosis, as well as the paradoxical association of extra-cellular $PP_i$ deficiency (from defective *ANKH* or ectonucleotide pyrophosphatase/phosphodiesterase 1 [ENPP1] expression) with pathologic calcification of articular cartilage with HA crystals in vivo. Factors driving pathologic calcification are indicated in green and physiologic factors suppressing calcification in red. Excess $PP_i$ generation in aging cartilages in idiopathic CPPD of aging and in OA cartilages is mediated in part by increased ENPP1. In idiopathic chondrocalcinosis of aging, mean cartilage $PP_i$ and nucleotide pyrophosphatase phosphodiesterase (NPP) catalytic activity levels are double normal. ENPP1 is markedly increased at sites of meniscal cartilage calcification in vivo, and NPP1 directly induces $PP_i$ elevation and matrix calcification by chondrocytes in vitro. Depending on extra-cellular availability of substrate $PP_i$ and the activity of the pyrophosphatase tissue-nonspecific alkaline phosphatase (TNAP), the availability of substrate ATP and the activity of ATPases, as well as other factors such as substantial local $Mg^{2+}$ concentrations and HA crystal deposition, as opposed to CPP crystal deposition, may be stimulated. In this model, excess extra-cellular $PP_i$ also may result from heightened "leakiness" of intra-cellular $PP_i$ via increased *ANKH* expression in OA and abnormal *ANKH* function in familial chondrocalcinosis. Also illustrated is the role in cartilage calcification in OA and aging of increased expression of cartilage intermediate layer protein-1 (CILP-1), which inhibits the capacity of insulin-like growth factor-I (IGF-I) to suppress elevation of extra-cellular $PP_i$. AMP, Adenosine monophosphate; TGF-β, transforming growth factor-beta.

the observation that radiographic evidence of CPPD at one joint is frequently associated with CPPD at distant joints, whether OA is present or not.[8,9] However, distant joint radiographic CPPD is frequently not the case for CPPD in hip OA, as opposed to knee OA.[8,9,11a,28a]

## Dysregulated $PP_i$ Metabolism in Pathologic Articular Cartilage Calcification

Dysregulated $PP_i$ metabolism, intimately linked with altered chondrocyte differentiation, function, and extracellular matrix homeostasis, is central to crystal deposition in idiopathic and other forms of CPPD. Unlike growth plate cartilage, articular cartilage, is specialized to avoid extra-cellular matrix calcification, in large part via abundant generation and release of $PP_i$ by chondrocytes, and constitutive suppression of the procalcifying hypertrophic chondrocyte differentiation state. $PP_i$ is a potent inhibitor of the nucleation and propagation of BCP crystals.[20] Concordantly, maintenance of physiologic extra-cellular $PP_i$ levels by chondrocytes and certain other cells serves to suppress calcification with HA, as illustrated in mouse models of deficient $PP_i$ generation and transport[22,23] and a variant of human infantile arterial calcification associated with periarticular calcification.[29] The relatively unique capacity of chondrocytes to produce copious amounts of extracellular $PP_i$ is double-edged (Figure 96-1), as supersaturation of cartilage extra-cellular matrix with $PP_i$ is a major factor in promoting CPP crystal deposition.[20,31] Furthermore, excess $PP_i$ generation can promote BCP crystal deposition by providing a source for increased extra-cellular $P_i$ generation via $PP_i$ hydrolysis by the ectoenzyme tissue-nonspecific alkaline phosphatase (TNAP)[20,23] (see Figure 96-1). Depending on cartilage ATP and $PP_i$ concentrations, as well as the level of activity of $P_i$-generating ATPases and TNAP, CPP, and hyaluronic acid (HA) crystal formation may be jointly promoted in cartilage, an event that commonly occurs clinically in OA.

Heterogeneous factors increase $PP_i$ generation in the joint space in aging and OA, but many converge on increasing articular and meniscal cartilage ectonucleotide pyrophosphatase phosphodiesterase (ENPP1) and the multiple-pass transmembrane protein ANKH.[20] These factors include dysregulated chondrocyte responses to the growth factors TGF-β and insulin-like growth factor-I (IGF-I).

## Role of ENPP1 and ANKH in $PP_i$ Metabolism in Chondrocalcinosis

Sporadic aging-associated CPPD is consistently linked with excess chondrocyte $PP_i$-generating ENPP activity and

augmented $PP_i$ generation by chondrocytes.[20,31,33] In this context, ENPP1 (formerly known as *NPP1* and *plasma cell membrane glycoprotein-1 [PC-1]*) and ENPP3 (formerly known as *B10*) actively generate $PP_i$ by hydrolysis of nucleoside triphosphates including ATP.[19,33] ENPP1 plays a central role in sustaining and augmenting extra-cellular $PP_i$ in chondrocytes and certain other cells (see Figure 96-1). A substantial portion of ATP used by chondrocytes to generate extra-cellular $PP_i$ is provided by the mitochondria.[19]

ENPP family enzymes share NPP catalytic activity and modular type II transmembrane ectoenzyme structures.[19,33] ENPP1 plays by far the greatest role in augmenting extracellular $PP_i$ in chondrocytes.[31,33] Significantly, total ENPP1 deficiency states in vivo and in vitro are associated with marked depletion of plasma and extra-cellular $PP_i$.[22,29,30] In contrast, in idiopathic CPPD, cartilage NPP activity and $PP_i$ levels may average approximately double those of healthy individuals.[34]

Increased ENPP1 expression is associated with both calcification and apoptosis in degenerative human cartilages.[31] Cartilage ENPP1 mRNA and protein staining and synovial fluid ENPP enzymatic activity have most often been reported as elevated in primary knee OA, although in more advanced primary OA with associated BCP crystal deposition, either decreased or increased cartilage chondrocyte ENPP1 mRNA has been described.[35,36] Direct upregulation of ENPP1 in chondrocytic cells stimulates calcification, as well as apoptosis.[37] These effects are not shared by ENPP3, which likely has other intra-cellular "housekeeping" functions in chondrocytes.[32] ENPP2, which is also expressed in normal cartilages, functions more actively in physiology as a lysophospholipase D, and ENPP2 only modestly stimulates chondrocytes to calcify in vitro.[31,32]

*ANKH* encodes a multiple-pass transmembrane protein that functions in $PP_i$ channeling[38-41] (Figure 96-2) and possibly ATP release[43] and regulation of $P_i$ metabolism and uptake by the type III sodium-dependent $P_i$ co-transporter Pit-1.[44] ANKH promotes bidirectional movement of $PP_i$ at the plasma membrane in vitro.[41] However, the gradient for ANKH-stimulated $PP_i$ movement in chondrocytes (which generate abundant $PP_i$ both by their robust ENPP1 expression and intense matrix biosynthetic activity) is from the intra-cellular to the extra-cellular space.[19] Indeed, ANKH transport of $PP_i$ generated intra-cellularly by ENPP1[26] may be the primary means to regulate extra-cellular $PP_i$ levels.[20] Modeling of the $PP_i$ channeling function of ANKH has proposed 10 or 12 membrane-spanning domains in ANKH with an alternating inside/out orientation and with a central channel to accommodate the passage of $PP_i$[38,40] (see Figure 96-2).

ANKH is implicated in both familial and idiopathic/sporadic CPPD,[12,13,16,17] and increased ANKH expression in cartilage is seen with primary CPPD as well as with secondary CPPD in primary knee OA[26,45] (see Figure 96-1). Hypoxia, via effects of the transcription factor hypoxia-inducible factor-1α, suppresses ANKH expression.[46] It is conceivable that increased permeability to oxygen of fibrillated and fissured cartilage in OA favors increased ANKH expression. Constitutive ANKH expression is functionally implicated in maintenance of chondrocytic differentiation by articular chondrocytes.[47] However, increased ANKH, in conjunction with signaling via extra-cellular $P_i$ likely

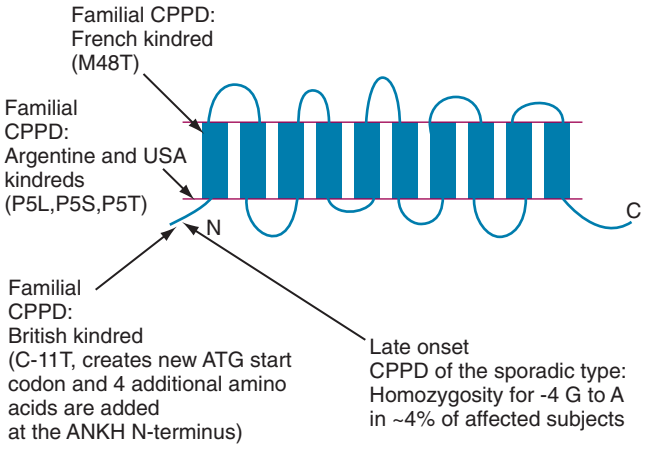

**Figure 96-2** Model for multiple-pass membrane protein structure of ANKH and for *ANKH* mutations associated with chromosome 5p-linked autosomal dominant familial calcium pyrophosphate dihydrate crystal deposition disease (CPPD) and heritable late-onset CPPD. The figure schematizes the putative multiple-pass transmembrane protein structure of ANKH, which appears to promote bidirectional proposed inorganic pyrophosphate ($PP_i$) movement between the cytosol to the extra-cellular space. The gradient for ANKH-stimulated $PP_i$ movement in chondrocytes (which generate abundant $PP_i$ both by high specific activity of ectonucleotide pyrophosphatase/phosphodiesterase 1 and robust matrix biosynthesis) is from the intra-cellular to the extra-cellular space. Distinct mutations in *ANKH* promote differences in age of onset and phenotypes in familial CPPD. The figure summarizes sites of known *ANKH* mutations clustered near the N-terminus that are associated with chromosome 5p-linked autosomal dominant familial CPPD, and all, except the French kindred M48T (which increases intra-cellular $PP_i$ and disrupts the association of ANKH with the inorganic phosphate transporter Pit-1), may act in part by increasing extra-cellular $PP_i$. A C-terminal domain *ANKH* mutation ΔE590 linked with one case of sporadic chondrocalcinosis is not depicted; *ANKH*ΔE590 appears to indirectly suppress $PP_i$ catabolism by association with impairing tissue-nonspecific alkaline phosphatase expression. The figure also depicts the –4 G to A transition in the 5′-untranslated region of *ANKH* for which homozygosity is seen in approximately 4% of late-onset sporadic CPPD, suggesting a small heritable subset. The N-terminally clustered *ANKH* mutations linked to CPPD all appear to promote chronic low-grade extra-cellular $PP_i$ excess resulting in CPP crystal formation, but there are differences in clinical and mineral metabolism phenotypes.

derived from $PP_i$, promotes chondrocyte maturation to the procalcifying hypertrophic differentiation state.[48] Figure 96-1 presents a model in which secondary alterations in chondrocyte expression of both wild-type ANKH and ENPP1 drive $PP_i$ supersaturation in cartilage in idiopathic/sporadic and OA-associated CPPD.

Mutations at different locations in *ANKH* can affect function and the skeleton in a manner including autosomal dominant CPPD[12,13,39-42] and certain other phenotypes. These include murine progressive ankylosis in the *ank/ank* mouse and human craniometaphyseal dysplasia associated with apparent decrease of the capacity to transport $PP_i$ within bone and effects on bone resorption and remodeling, putatively mediated in part by direct and indirect effects on osteoclasts.[38,41,49] In a consanguineous family with mental retardation, deafness, and ankylosis, with painful small joint soft tissue calcifications, progressive spondyloarthropathy, osteopenia, and mild hypophosphatemia, the homozygous *ANKH* missense mutation L244S was detected in all patients.[50] The mutant ANKH protein was expressed and

localized to the plasma membrane, but fibrosis and mineralization of articular soft tissues developed in homozygotes, with heterozygous carriers of the L244S mutation showing mild osteoarthritis without metabolic alterations.[50]

Clinical heterogeneity, even for CPPD associated with *ANKH* mutations,[12,13] suggests differing functional effects of ANKH mediated by specific regions of the molecule. Most of the N-terminally clustered *ANKH* coding region mutations identified to cause familial CPPD (see Figure 96-2) increase $PP_i$ transport *in vitro*.[12,13,39,40] However, some *ANKH* mutations have distinct effects on chondrocyte differentiation.[16] The M48T *ANKH* mutant in the French kindred appears functionally unique by association with increased intra-cellular $PP_i$ and interrupting interaction of ANKH with the sodium/phosphate cotransporter Pit-1.[51] This may be functionally significant because elevated $P_i$ increases both ANKH and Pit-1 expression, because ANKH and Pit-1 colocalize in chondrocytes,[51] and because $P_i$ modulates chondrocyte differentiation. An alternative mechanism of disrupting $PP_i$ metabolism may be promoted by the *ANKH* mutation ΔE590 linked with a case of sporadic CPPD[14] because *ANKH*ΔE590 appears to indirectly suppress $PP_i$ catabolism by association with impairing TNAP expression.[52] Uniquely, the familial CPPD *ANKH* mutation encoding P5S amino acid substitution was linked with secondary hyperparathyroidism and phosphaturia.[42]

Homozygosity for a single nucleotide substitution (−4 G to A) in the *ANKH* 5-untranslated region that promotes increased *ANKH* messenger RNA expression was present in approximately 4% of British subjects previously thought to have idiopathic/sporadic CPPD of aging.[16] Association with CPPD of this same noncoding region single base pair substitution was confirmed in a hospital-based study, and was independent of patient age and OA.[17]

## Imbalance of Chondrocyte Growth Factor Responses Affects $PP_i$ Metabolism in CPPD

The chondrocyte anabolic growth factor TGF-β stimulates ATP release by chondrocytes,[43] as well as ENPP1 expression and ENPP1 subcellular movement to the plasma membrane, which drive elevation of extra-cellular $PP_i$.[32] IL-1β suppresses both ENPP1 expression and extra-cellular $PP_i$ in chondrocytes and blocks the effects of TGF-β on $PP_I$.[32] The capacity of TGF-β to raise chondrocyte $PP_i$ increases with aging, as does TGF-β–stimulated NPP activity,[53] whereas growth-promoting effects of TGF-β decrease with aging in articular chondrocytes. These changes are potentially mediated by known alterations in TGF-β receptor–subunit expression in aged chondrocytes.

IGF-I, also an anabolic chondrocyte growth factor, normally suppresses extra-cellular $PP_i$ (as well as ATP release)[43] in chondrocytes (see Figure 96-1). Significantly, chondrocyte IGF-I resistance is characteristic of OA and aging cartilages[54] (see Figure 96-1). One mechanism pertinent to CPPD is that IGF-I induces cartilage intermediate-layer protein (CILP) (see Figure 96-1), the expression of which increases in aging and OA and is most abundant in the middle zone of articular cartilage where CPPD is most prevalent. CILP-1, but not the CILP-2 isoform, promotes increased extra-cellular $PP_i$ in chondrocytes indirectly by inhibiting IGF-I at the receptor level.[54]

## CPPD Deposition Disease Secondary to Primary Metabolic Disorders: Relationship to $PP_i$ Metabolism and Chondrocyte Differentiation

Hypophosphatasia, hypomagnesemic conditions (including the Gitelman's variant of Bartter's syndrome), hemochromatosis, and hyperparathyroidism are the best characterized primary metabolic disorders linked to secondary CPPD. Increased joint fluid $PP_i$ levels in each of these conditions suggests at least one common thread in the pathogenesis of chondrocalcinosis via cartilage $PP_i$ excess.[55] Magnesium is a cofactor for pyrophosphatase activity, and iron excess can suppress pyrophosphatase activity.

Hypercalcemia may promote CPP crystal deposition in hyperparathyroidism (and in familial hypocalciuric hypercalcemia)[56] by effects beyond cartilage matrix supersaturation with ionized calcium such as calcium function as a cofactor in ENPP1 catalytic activity, as well as chondrocyte-activating effects mediated by calcium transport[28] and the calcium-sensing receptor.[25] In addition, normal articular chondrocytes express parathyroid hormone/parathyroid-hormone-related protein (PTH/PTHrP) receptors, and functional responses of chondrocytes to PTH can promote proliferation, altered matrix synthesis, and mineralization.

Hypophosphatasia is the result of deficient activity of TNAP, with effects including limitation of hydrolysis $PP_i$ to generate $P_i$.[23] TNAP is a major physiologic antagonist of ENPP1-mediated elevation of extra-cellular $PP_i$.[23] Conversely, physiologic ENPP1-induced $PP_i$ generation antagonizes the essential procalcifying effects of TNAP mediated by $P_i$ generation,[23] and cartilage $PP_i$ excess presumably drives chondrocalcinosis in hypophosphatasia. *Enpp1* knockout mice and mice homozygous for the ENPP1 truncation mutant *ttw* demonstrate marked articular cartilage calcification with HA and OA, as well as ankylosing spinal ligament hyperostosis and synovial joint ossific fusion. Extra-cellular $PP_i$ levels and mineralization disturbances in soft tissues (but not long bones) of *Enpp1* knockout and TNAP-deficient mice are mutually corrected by cross-breeding.[23]

## Inflammation and Hypertrophic Chondrocyte Differentiation in Chondrocalcinosis

Regulated changes in chondrocyte differentiation and viability appear to be a mechanistically unified process that promotes joint cartilage HA and CPP crystal deposition, as well as OA. Such changes include development of foci of chondrocyte maturation to hypertrophy, with the presence of hypertrophy, as seen in histopathology of the knee cartilage in Figure 96-3, and apoptosis of chondrocytes typically found adjacent to cartilage calcifications. Articular chondrocyte hypertrophy is associated with heightened $PP_i$ generation; increased production of calcifying, membrane-limited cell fragments known as *matrix vesicles*; and certain other calcification-promoting changes in differentiation, including alteration of extra-cellular matrix composition. For example, osteopontin (which promotes CPP crystal formation) is increased and normal collagen subtype composition in the matrix is lost. TGF-β normally suppresses development of articular chondrocyte hypertrophy. Hence, altered TGF-β signal transduction in aging and OA may be involved in promoting chondrocyte hypertrophy.

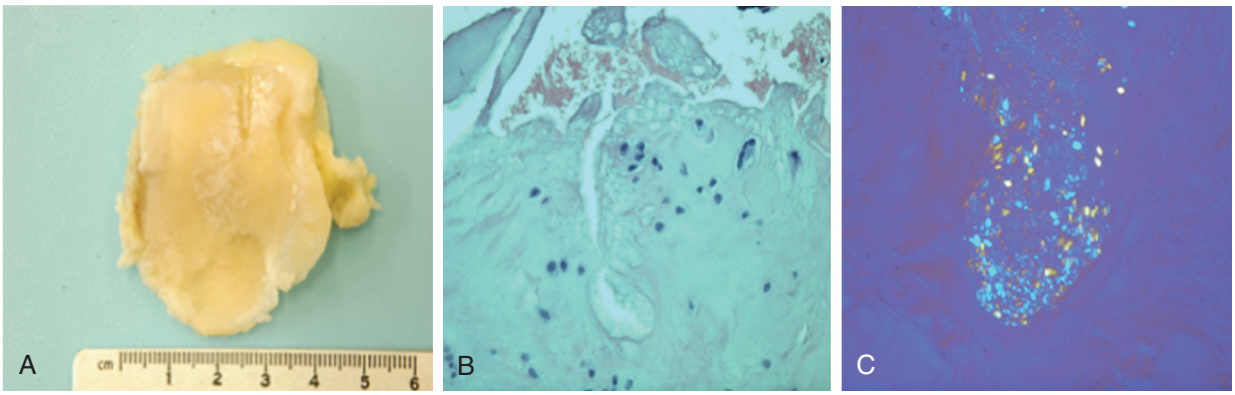

**Figure 96-3** Calcium pyrophosphate dihydrate crystal deposition disease (CPPD) arthropathy of the knee joint. **A,** Femoral condyle. There are extensive foci of chalky white particulate deposits within the articular cartilage. This is characteristic of CPPD. **B,** Histology of CPP crystal deposition within the hyaline articular cartilage. The hypertrophic chondrocytes adjacent to the crystal aggregates are within enlarged chondrons (hematoxylin and eosin, original magnification ×250). **C,** Polarized light microscopy of CPP crystal aggregates within the hyaline articular cartilage. The individual crystals have rod and rhomboid shapes and are positively birefringent (original magnification ×250). *(Courtesy Dr. Ken Pritzker, Mount Sinai Hospital Pathology Department, University of Toronto, Ontario, Canada.)*

$P_i$ taken up by Pit-1 sodium-dependent cotransport and calcium sensing can modulate chondrocyte hypertrophic differentiation and apoptosis, as well as $PP_i$-modulating responses to TGF-β.[20,31,57-59] Local upregulation of PTHrP expression also may be one of the shared features driving sequential chondrocyte proliferation and altered differentiation in growth plate chondrocytes and articular chondrocytes.[25] Chondrocyte apoptosis also promotes calcification partly through the calcifying potential of apoptotic bodies functioning as "inside-out" matrix vesicles on release from dying chondrocytes. Mitochondrial dysfunction, a central factor in tissue aging and an apparent mediator of OA progression in aging, also can stimulate oxidative stress and inflammatory changes, as well as cartilage matrix degeneration and calcification. Mitochondria are remarkably specialized to regulate calcification, and apoptosis is critically regulated by mitochondrial function. Moreover, chondrocyte ATP depletion is driven via suppression of mitochondrial oxidative phosphorylation by nitric oxide (NO) while OA evolves during aging, thereby promoting increased ATP scavenging by NPP activity and consequent augmentation of extra-cellular $PP_i$.[60]

IL-1β, which is increased in OA cartilage, stimulates articular chondrocytes to calcify the matrix.[53] NO stimulates both apoptosis and calcification in chondrocytes IL-1β and stimulates inducible nitric oxide synthase (iNOS) expression and increased NO generation, as well matrix alterations. IL-1β (as well as TNF, certain chemokines, donors of NO, and the potent oxidant peroxynitrite) also induces increased chondrocyte procalcifying transglutaminase activity.[53] TG2 acts in part by directly and indirectly promoting chondrocyte hypertrophy,[65] and also promotes activation of TGF-β.

## Special Pathogenic Aspects of Articular and Periarticular Basic Calcium Phosphate Crystal Deposition

BCP crystal deposition occurs in most hip OA, as detected by digital contact radiography, whereas plain radiography detects calcification in cartilages of less than 20% of hips of patients with OA.[61] BCP crystals also are commonly detectable within human knee cartilages with end-stage primary OA,[62,63] contribute to mineral content that can comprise 5% to 10% of knee articular cartilage weight, and typically involve multiple articular cartilage zones (including weight bearing and nonweight bearing in knee OA).[36] The process probably involves BCP crystal deposition in multiple phases of chondrocyte differentiation and functional changes, as well as viability loss. In this context, abundant cartilage NO production in OA may promote mitochondrial dysfunction, chondrocyte extra-cellular ATP depletion,[61] and lowering of extra-cellular $PP_i$, consequently favoring BCP versus CPP crystal deposition.[20] Conversely, joint fluid $PP_i$ and NPP activity are elevated in BCP-crystal–associated shoulder arthropathy (Milwaukee shoulder syndrome [MSS]), consistent with the model in Figure 96-1.

Pathologic BCP crystal deposition may occur in periarticular sites, as well as numerous organs and soft tissues. Significantly, the shoulder is the most common articular region affected by symptomatic BCP crystal deposition, in part reflecting unique shoulder structure-function (see Chapter 46). Degenerative changes promoted by biomechanical stress promote calcific tendinitis in the body of the rotator cuff. Such tendon calcifications can remain asymptomatic and also can eventually resorb, but the degenerative changes can predispose to tendon rupture. Osteopontin, a factor that normally restrains BCP crystal deposition (and is regulated by $PP_i$ and $P_i$),[22] can be detected in fibroblast-like cells and multinucleated macrophages surrounding areas of calcification in calcific tendinitis.[65] In this regard, osteopontin promotes oxidative stress, MMP activation, and macrophage recruitment and osteoclast activation.[22] The presence of multinucleated cells with cathepsin K expression and osteoclast-like functions at sites of tendon calcification[66] suggests a mechanism for both resorption of BCP crystal deposits and tendon degeneration.

## Crystal-Induced Inflammation

Some of the crystals deposited in cartilage (see supplemental Figure 96-1 on ExpertConsult.com) can subclinically

traffic to joint fluid and synovium, and the crystals can directly stimulate chondrocytes, synovial lining cells, and intra-articular leukocytes.[67-73] Inflammation triggered by CPP and BCP crystals thereby can contribute to acute flares of OA, and has the capacity to contribute to synovitis, cartilage degradation, and to potentiate worsening of OA.[67-73] Nevertheless, the net role of CPP and BCP crystals in promoting human OA progression is not well characterized.

Many pro-inflammatory mechanisms active in gout also likely mediate synovitis and cartilage degeneration associated with CPP and BCP crystal deposition.[67-73,75-78] In this regard, CPP and BCP crystals activate cells partly via non-specific activation of signal transduction pathways (e.g., mitogen-activated protein kinase activation) and induce cellular release of cyclooxygenase- and lipoxygenase-derived metabolites of arachidonic acid, cytokines including TNF, IL-1, and CXCL8[67-73] and multiple extra-cellular matrix-degrading proteases. Innate immune engagement of extracellular CPP crystals by Toll-like receptor (TLR)2[77] and CPP and BCP crystal-induced activation of the intra-cellular NLRP3 (cryopyrin) inflammasome, resulting in caspase-1 activation and IL-1β processing and release, drive cell responses to CPP and some, but not all, forms of BCP crystals in vitro and crystal-induced inflammation in vivo.[74,75,76]

In chondrocytes, BCP crystal deposits and IL-6 mutually promote each other's expression, leading to OA changes in vitro and in vivo.[76a]

The ingress of neutrophils into the joint is central in triggering acute crystal-induced synovitis, and the effects on neutrophil-endothelial interaction likely represent a major locus for prophylactic effects of low doses of colchicine for the acute arthritis of pseudogout. CXCL8 and related chemokines that bind the CXCL8 receptor CXCR2 (including CXCL1) appear to be critical in initiating and perpetuating neutrophil ingress in acute crystal-induced inflammation. However, "neutrophil extra-cellular trap" formation, an NADPH oxidase- and CXCR2 chemokine ligand-mediated process stimulated by CPP and urate crystals, is likely involved in self-limiting of acute CPP crystal-induced inflammation.[79,80]

Periarticular BCP crystals have marked inflammatory potential, such as in acute subacromial bursitis (see Chapter 46). However, BCP crystals generally trigger much less neutrophil influx into the joint space than CPP crystals. Concordantly, free intra-articular BCP crystals likely induce less pro-inflammatory cytokine expression than CPP and monosodium urate crystals, although OCP crystals could be more inflammatory than hydroxyapatite crystals.[76]

## CLINICAL FEATURES

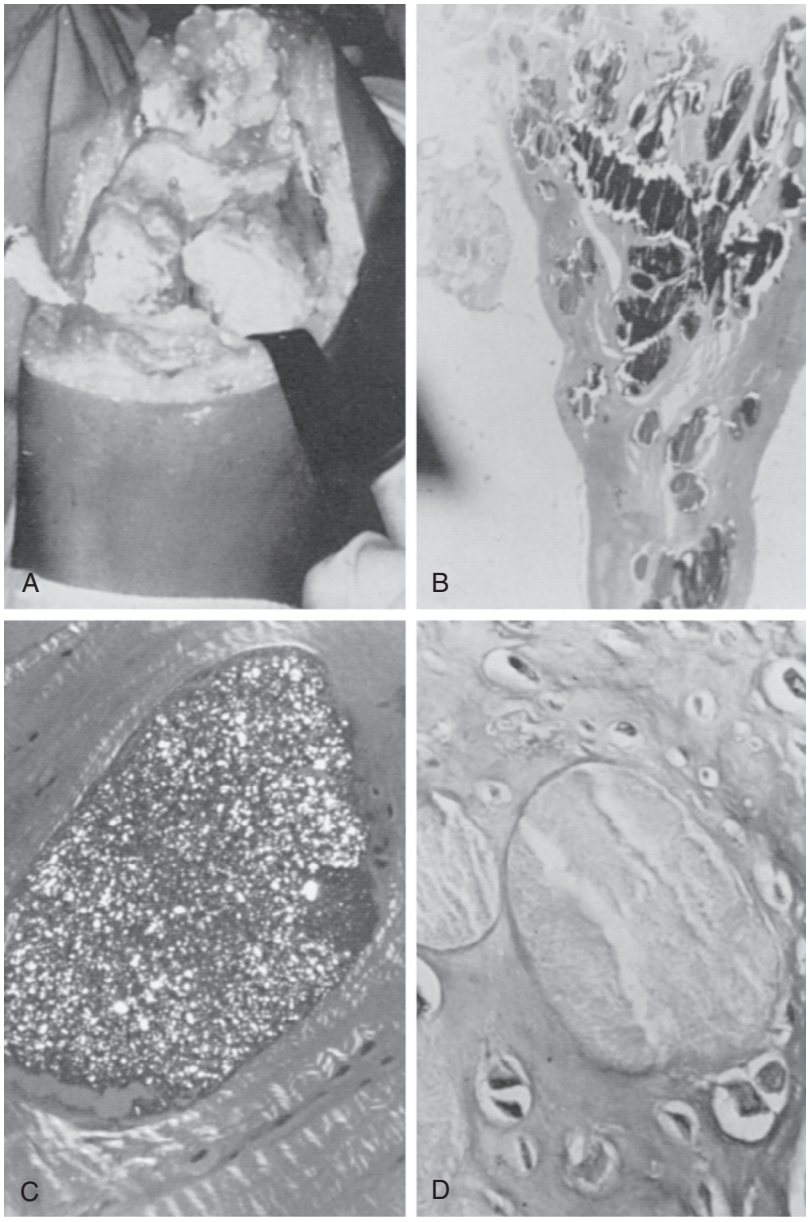
### KEY POINTS

**In the elderly, CPPD can mimic conditions including gout, infectious arthritis, primary osteoarthritis, rheumatoid arthritis (RA), or polymyalgia rheumatica.**

**CPPD can present as fever of unknown origin, and factor in the differential diagnosis of patients with neurologic disturbances and painful cervical mass, especially in the elderly.**

**Acute CPP arthritis (also termed *pseudogout*) is a major cause of acute monoarticular or oligoarticular arthritis in the elderly. Attacks typically involve a large joint, most often the knee, less often, the wrist or ankle, and, unlike gout, rarely the first metatarsophalangeal joint.**

**Chronic degenerative arthropathy in CPPD commonly affects certain joints that are typically spared in primary OA (e.g., metacarpophalangeal joints, wrists, elbows, glenohumeral joints).**



### Calcium Pyrophosphate Dihydrate Crystal Deposition Disease

The majority of elderly individuals with CPPD in the United States have primary (idiopathic/sporadic) CPPD or CPPD secondary to OA (Table 96-2). Idiopathic CPPD generally appears only after the fifth decade of life. However, patients with a history of repetitive joint trauma (and in some cases, past knee meniscectomy) may be seen with nonsystemic (monoarticular) CPPD before age 55 years. Clinical presentation of familial CPPD is often manifested in the third and fourth decades of life, but familial disease can sometimes be detected before age 20 years or first manifest clinically at an advanced age. CPPD also manifests in a variety of hereditary and metabolic conditions (including hyperparathyroidism, dialysis-dependent renal failure, and hemochromatosis) in which the CPPD-related arthropathy can be seen in patients younger than age 55 years. For unclear reasons, hemochromatosis can manifest predominantly with CPPD or as OA. The weight of evidence from

controlled studies suggests that hypothyroidism (with the probable exception of myxedematous hypothyroidism) is not associated with a significantly increased prevalence of CPPD, although both disorders are clearly prevalent in aging. Initiation of thyroxine supplementation therapy has been suggested as a trigger of pseudogout.

Clinical manifestations of CPPD vary widely[81] (Table 96-3). Quite commonly, CPPD is asymptomatic. Alternatively, it can mimic OA (pseudo-osteoarthritis), gout (pseudogout) (see supplemental Figure 96-2 on ExpertConsult.com), acute-onset or insidious RA (pseudorheumatoid arthritis) (Figure 96-4; see also supplemental Figure 96-3 on ExpertConsult.com), or be seen as *pseudoneuropathic* arthropathy. Patients with CPPD also commonly are seen with episodes of hemarthrosis, often post-traumatic and in the knee. Contributions to these wide differences in clinical manifestations of monoclinic versus triclinic CPP crystals deposited, and of host factors, remain unclear. Overall, few patients with CPPD have prolonged, recurring polyarticular inflammation. Progressive degenerative arthropathy is more common. Although CPPD appears to be a common and significant public health problem in the elderly, the disease and health-related quality of life impact and the long-term course of CPPD-associated degenerative arthropathy in an unselected population have not been adequately evaluated.

**Table 96-3** Common Clinical Presentations of CPPD

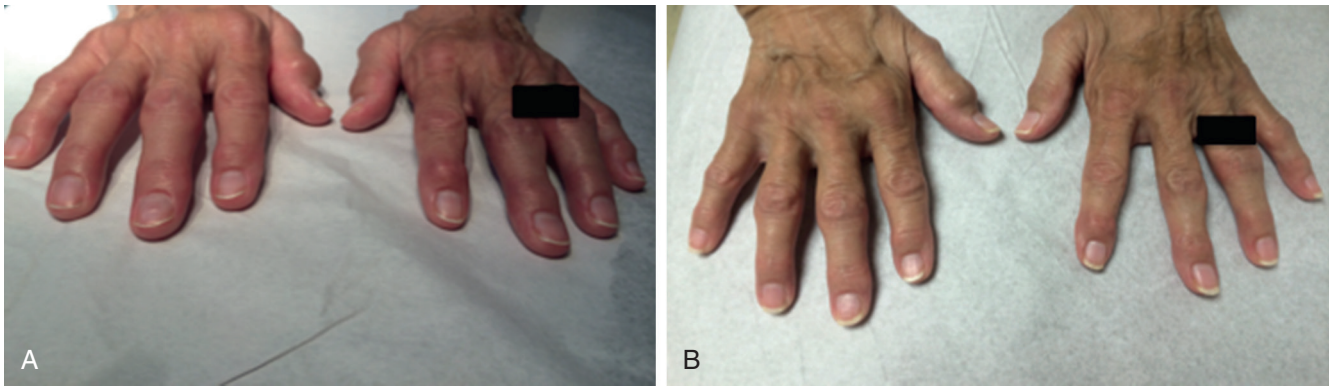
| |
|---|
| Asymptomatic or incidental finding (e.g., asymptomatic knee fibrocartilage chondrocalcinosis in the elderly) |
| Recurrent acute inflammatory monoarticular arthritis (pseudogout) (e.g., wrist, knee, including provocation by trauma, concurrent medical or surgical illness, or intra-articular hyaluronan) |
| Pseudoseptic arthritis: includes inflammatory arthritis early and late after total joint arthroplasty |
| Recurrent acute hemarthrosis |
| Chronic degenerative arthritis (pseudo-osteoarthritis or pseudo-neuropathic arthritis) |
| Chronic symmetric inflammatory polyarthritis (pseudorheumatoid arthritis) |
| Systemic illness (pseudopolymyalgia rheumatica, fever of unknown origin) |
| Destructive arthritis in dialysis-dependent renal failure |
| Carpal tunnel syndrome |
| Central nervous system disease complicating ligamentum flavum or transverse ligament of atlas involvement (cervical canal stenosis, cervical myelopathy, meningismus, foramen magnum syndrome, odontoid fracture) |
| Tumoral and pseudotophaceous CPP crystal deposits |

CPPD, Calcium pyrophosphate dihydrate crystal deposition disease.

## Acute Calcium Pyrophosphate Dihydrate Crystal-Associated Synovitis (Pseudogout)

Pseudogout is a major cause of acute monoarticular or oligoarticular arthritis in the elderly. The attacks typically involve a large joint, most often the knee and less often the wrist or ankle, and, unlike gout, rarely the first metatarsophalangeal joint. Acute attacks of inflammatory pseudogout in patients with CPPD typically have a sudden onset and can be excruciatingly painful, with pronounced periarticular erythema, warmth, and swelling, comparable to gout.[1,81] In addition, arthritis in some attacks of pseudogout can be migratory or can be additive, polyarticular, and bilateral. Polyarticular pseudogout is common in familial CPPD and hyperparathyroidism.

Multiple case reports indicate that CPP inflammatory arthritis, often acute and sometimes mimicking a septic joint, can develop early or even many years after total joint arthroplasty of a joint affected by CPPD[82,83,84,85,86]; development of calcification in areas of chondroid metaplasia in the joint, including around the prosthesis, appears to be involved.[87] Acute CPP inflammatory arthritis also can be triggered by minor trauma or intercurrent medical or surgical conditions including pneumonia, myocardial infarction, cerebrovascular accident, and pregnancy. Parathyroid surgery for hyperparathyroidism frequently triggers pseudogout attacks. In addition, pseudogout of the knee can be precipitated by arthroscopy or by intra-articular administration of hyaluronan[88] that could reflect pro-inflammatory mechanisms triggered through the hyaluronan receptor CD44. Parenteral administration of granulocyte colony-stimulating factor (G-CSF) and of bisphosphonates[89] also can trigger pseudogout, the former likely by ignition of



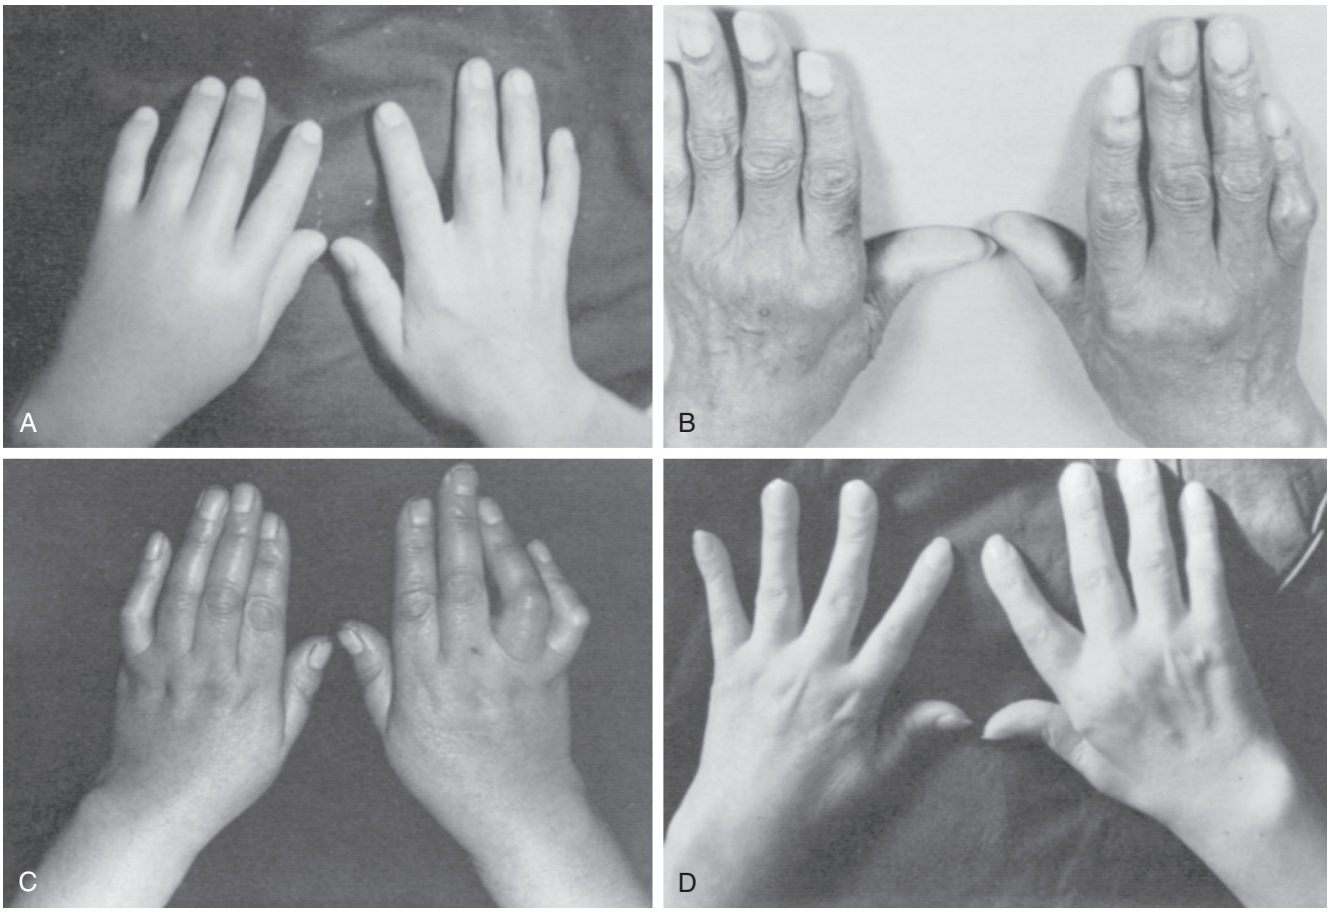


**Figure 96-4** Idiopathic symmetric pseudorheumatoid calcium pyrophosphate dihydrate crystal deposition disease (CPPD) darthropathy in an elderly female. This 66-year-old female presented with a 4- year history of hand pain, and manifested chronic symmetric proliferative synovitis diffusely involving both metacarpophalangeal (MCP) joint and proximal interphalangeal (PIP) joint rows **(A)**, and had plain radiography and ultrasound findings consistent with CPPD. After 6 months of treatment with low-dose methotrexate and hydroxychloroquine, she was symptomatically better, with decreased MCP joint row swelling and improved, although with persistent, PIP joint row swelling **(B).**

**Supplemental Figure 96-2** **A**, Acute pseudogout. The patients in **A, C,** and **D** are siblings. **B,** Pseudo-osteoarthritis. **C,** Pseudorheumatoid arthritis with boutonnière deformity. **D,** Pseudorheumatoid arthritis showing ulnar deviation, interosseous muscle atrophy, and metacarpophalangeal and wrist joint involvement.

**Supplemental Figure 96-3** Idiopathic symmetric pseudorheumatoid calcium pyrophosphate dihydrate (CPPD) deposition arthropathy in an elderly female. This 84-year-old female presented with a history of past right carpal tunnel syndrome and with chronic symmetric proliferative synovitis of both wrists and second and third metacarpophalangeal (MCP) joints, with physical findings of synovial and dorsal extensor tenosynovial swelling of the wrists and synovial swelling at the second to third MCP joints **(A).** Changes on hand and wrist plain radiographs consistent with the diagnosis of CPPD deposition disease, presented for the right wrist **(B),** included cystic changes in multiple carpal bones including the scaphoid and lunate, linear calcification on the ulnar side of the carpus *(arrow)* typical for the chondrocalcinosis of CPPD deposition, and mild narrowing of the radiocarpal joint indicative of cartilage loss.

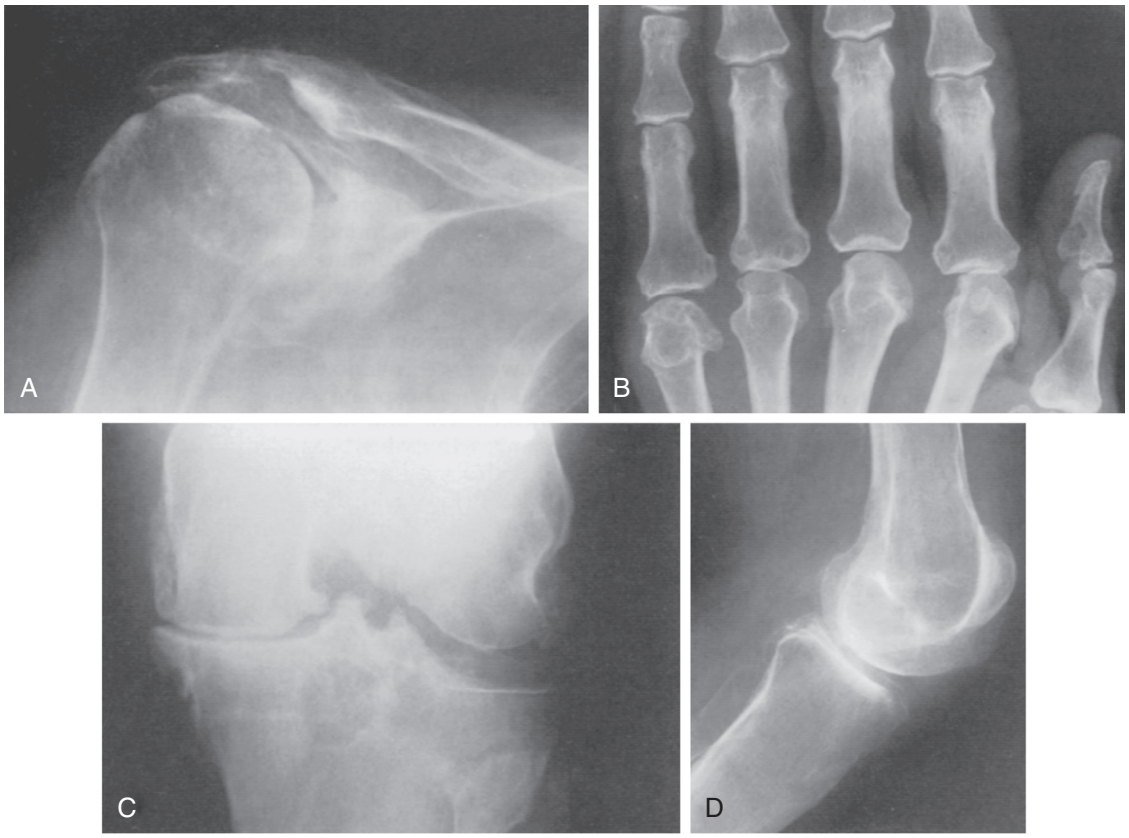

**Figure 96-5** Radiographic features of calcium pyrophosphate dihydrate crystal deposition disease (CPPD) arthropathy. **A,** Destructive shoulder arthropathy. **B,** Metacarpophalangeal joint arthropathy. **C,** Knee degenerative joint disease with large subchondral bone cyst. **D,** Wraparound patella (same patient shown in **A**).

smoldering subclinical intra-articular inflammation, the latter theoretically via pyrophosphatase inhibition, because bisphosphonates are nonhydrolyzable analogues of $PP_i$.

Acute and subacute pseudogout can be associated with fever, chills, elevated erythrocyte sedimentation rate, and systemic leukocytosis, particularly with polyarticular involvement and in the elderly.[1] Leukocyte counts in the synovial fluid are substantially elevated, and intraleukocytic CPP crystals are most often (but not universally) detectable by compensated polarized light microscopy in acute CPP arthritis (pseudogout).[1] The attacks typically last for 7 to 10 days, but also can be clustered and last for weeks to months. Occasionally, the leukocyte count in pseudogout can exceed 50,000 per $mm^3$ (pseudoseptic arthritis).

## Chronic Degenerative and Inflammatory Arthropathies

Acute pseudogout attacks may be interspersed with chronic arthropathy in CPPD, although acute flares of pseudogout may be less common in those with established chronic degenerative CPPD.[90] Chronic degenerative arthropathy in CPPD commonly affects certain joints that are typically spared in primary OA (e.g., metacarpophalangeal joints, wrists, elbows, glenohumeral joints). The development of cartilage degenerative changes in CPPD in both typical and atypical joints for primary OA suggests one or more systemic abnormalities. Significantly, the linkage of CPPD and OA is quite variable between joints.[11a]

Degenerative cartilage disease associated with sporadic CPPD may be seen as destructive arthropathy of the knees, hips, and/or shoulders, particularly in elderly females (Figures 96-5 and 96-6). The CPPD arthropathy–associated degenerative disease can be less or more destructive than that observed in primary OA. For example, patients with primary OA and CPP crystals have been reported to require knee replacement surgery more often than those with primary OA without crystals.[91] In another study, 60% of patients undergoing joint replacement had CPP or BCP crystals (and commonly both) in their knee synovial fluids, and higher mean radiographic scores correlated with the presence of calcium-containing crystals.[92] However, radiographic worsening of degenerative changes is often slow. Most patients develop changes in radiographic extent of chondrocalcinosis with time. But there is no clear correlation between the extent of calcification and progression of CPPD arthropathy. It remains unclear whether the prognosis is altered by the initial appearance of CPPD in the knee as an acute pseudogout attack alone.

Though it is not clear how CPPD modified the clinical phenotype of OA, it does appear to be associated with modifications of the radiographic phenotype.[28a] Specifically, CPPD appears to be associated with decreased knee bone stock when present in knee OA, putatively mediated in part by local PPi excess. Moreover, in a cohort study of severe symptomatic large joint OA, there was a milder imaging phenotype of hip OA linked with CPPD, with negative association seen between osteophytosis and JSN at the hip

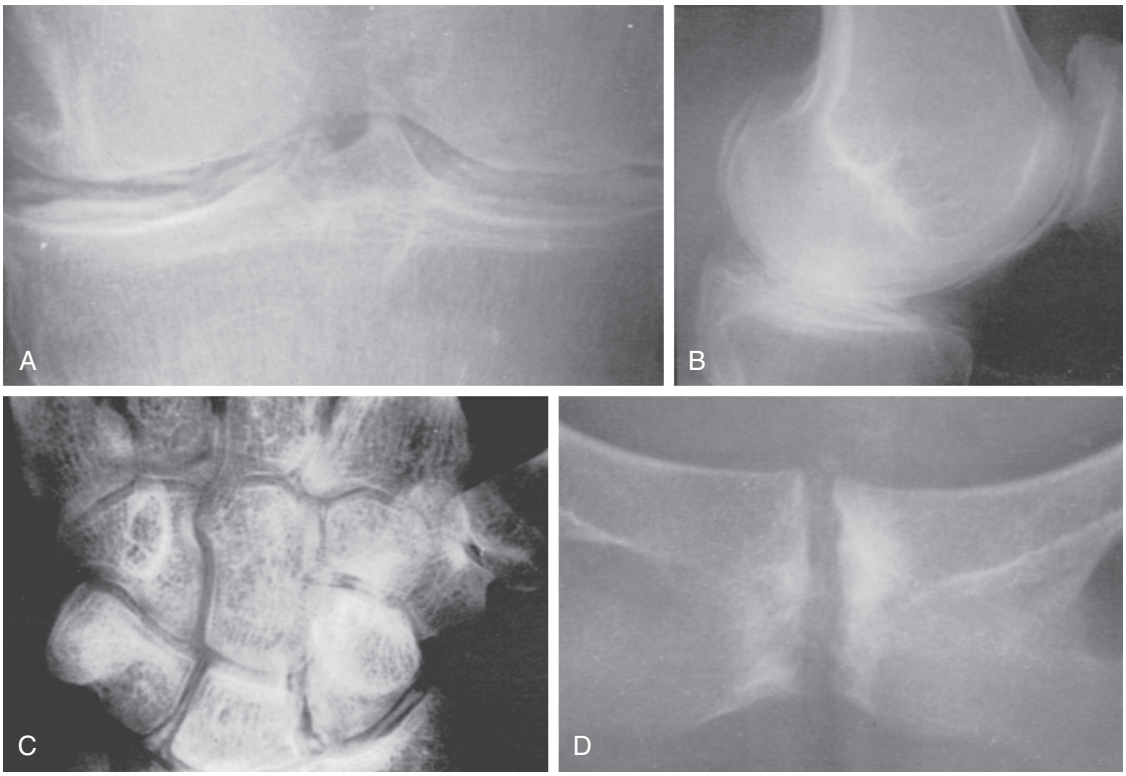

**Figure 96-6** Chondrocalcinosis of the most commonly affected joints in calcium pyrophosphate dihydrate crystal deposition disease (CPPD). **A,** Linear calcifications observed in knee menisci and fibrocartilage. **B,** Lateral view showing calcification of the articular cartilage as a line parallel to the femoral condyles. **C,** Calcification of intercarpal joints and triangular ligament. **D,** Calcification of the symphysis pubis fibrocartilage associated with subchondral bone erosions and subchondral increased bone density.

and hip CPPD, assessed by plain radiography. However, this work, in a hospital cohort, needs larger validation, since the findings may reflect difficulty in visualizing CPPD by plain radiography in more advanced hip OA, due to marked articular cartilage loss.

Pseudorheumatoid arthritis involvement in a small subset of patients with CPPD appears as a chronic, bilateral, symmetric deforming inflammatory polyarthropathy (see Figure 96-4). Many of these patients have bilateral wrist and metacarpophalangeal joint involvement. Wrist tenosynovitis and carpal tunnel syndrome, cubital tunnel syndrome, and tendon rupture may develop. Ingestion of CPP crystals by synovial lining cells and lysosomal catabolism of such ingested crystals stimulates synovial proliferation, in part via solubilization of the crystalline calcium. Such effects may contribute to regional synovial and periarticular tenosynovial proliferation promoted by CPP crystal deposition.

## Other Clinical Forms of CPPD

Concentrated (tumoral or pseudotophaceous) CPP crystal deposition can occur in periarticular structures including tendons, ligaments, bursae, and occasionally in bone.[93,94,95] Extraskeletal CPP crystal disease can occur, but appears rare.[96] CPP crystal deposits in tendons (e.g., Achilles, triceps, and obturator tendons) are usually fine and linear on radiographs. Pseudotophaceous deposits of CPP crystals have been detected in the temporal bone, around the knee and hip, and in the acromioclavicular, temporomandibular, elbow, and small hand joints. [93,94,95] Peripheral tumoral CPP crystal deposits may sometimes manifest with acute arthritic attacks. Rarely, tumoral CPP crystal deposits around the knee can mimic osteonecrosis. Tumoral CPP crystal deposition is typically associated with tissue chondroid metaplasia and behaves like a benign but locally aggressive chondroid tumor, with some of the connective tissue invasion and destruction likely mediated by CPP crystal-induced cell activation.

Axial skeletal CPPD occasionally involves the intervertebral disks, sacroiliac joints, and lumbar facet joints, and radiographic findings such as linear calcification and spinal ankylosis may appear.[97,98,99] CPPD also commonly factors in the differential diagnosis of patients with neurologic disturbances and painful cervical mass, especially in the elderly. Specifically, meningismus and clinical manifestations resembling herniated intervertebral disk, ankylosing spondylitis, and acute pseudogout of lumbar facet joints have been observed.[100] In addition, CPP crystal deposits are common in the antlanta-axial joint in aging.[101] CPPD within the ligamentum flavum or the transverse ligament of atlas can be sizeable and can progress to cause cervical canal stenosis, cervical myelopathy, and foramen magnum syndrome.[102,103] Odontoid fracture because of the calcification of the atlantoaxial joint may occur in CPPD.[103,104]

## Familial CPPD

Familial CPPD has been described in numerous countries and ethnic groups, including kindreds from Czechoslovakia, Holland, France, England, Germany, Sweden, Israel, the

United States, Canada, and Japan, and may be most prevalent in Chile and Spain. For linkages to *ANKH* on chromosome 5p, some families manifest early onset polyarthritis, which can include ankylosing intervertebral and sacroiliac joint disease, and childhood seizures have been described.[13,15,40] In others, late-onset CPPD occurs, and the disease can be oligoarticular, mild in intensity and destructiveness, and nearly indistinguishable from idiopathic CPPD.[13,15,40] Kindreds from Argentina and the Alsace region of France linked to 5p have been found to share similar phenotypic features of CPPD, including early age at onset (third decade of life), common but not universal premature OA, some cases of pseudorheumatoid arthritic peripheral joint disease, and radiographic evidence of fibrocartilage and hyaline cartilage calcifications typical of CPP crystal deposition. The most commonly affected joints in these kindreds were the knees and wrists, with pubic symphysis and intervertebral disk involvement also described.

## ARTICULAR BASIC CALCIUM PHOSPHATE CRYSTAL DISEASE

### KEY POINTS

**Unlike urate and CPP crystal deposition, acute synovitis because of HA crystal deposition is unusual. However, acute periarticular inflammatory syndromes including subacromial bursitis and a form of pseudopodagra described in young women may occur in association with HA crystal deposition in bursae, tendons, ligaments, and soft tissues.**

**Symptomatic articular and periarticular BCP crystal deposition, which may be destructive and involve the axial skeleton, may develop in patients with advanced chronic renal failure, particularly on dialysis. They may resemble or be associated with CPPD.**

Unlike urate and CPP crystal deposition, acute synovitis due to HA crystal deposition is unusual. But acute inflammatory syndromes including subacromial bursitis and "pseudopodagra" may occur in association with periarticular HA crystal deposition in bursae, tendons, ligaments, and soft tissues. Symptomatic articular and periarticular BCP crystal deposition may develop in patients with advanced chronic renal failure, particularly on dialysis (Figure 96-7), which may be destructive and involve the axial skeleton. In some cases of dialysis-dependent renal failure, destructive arthropathy associated with BCP crystal deposition may resemble or be associated with CPPD, and monosodium urate crystal deposits in the joint also may occur in the setting. Hyperparathyroidism can promote BCP-associated arthropathy and periarticular disease including calcific bursitis (see Figure 96-7). Clinically significant periarticular HA crystal deposition also may occur in certain post-traumatic conditions and the systemic autoimmune diseases scleroderma and dermatomysositis.

BCP crystal deposition has a particular predilection for the shoulder (see Chapter 46), where it may manifest as calcific tendinitis of the rotator cuff or as a destructive process associated with rotator cuff tear, which is most prevalent in the elderly and more common in females.[105] Abundant intra-articular BCP crystalline material is typically present in the distinctive non-inflammatory syndrome of rotator cuff tear and marked cartilage degeneration, an entity termed *MSS, cuff tear arthropathy*, or *apatite-associated destructive arthritis*.[105] Mechanical instability of the shoulder because of rotator cuff tear may be the driving force in many of these patients, with consequent release of BCP crystals from bone fragments into the joint space, promoting secondary synovitis and connective tissue destruction. The process may be bilateral but is generally worse on the side of the patient's dominant hand. Substantial glenohumeral joint effusions are typically seen, and synovial fluid is often blood stained but contains, at most, relatively low numbers of mononuclear leukocytes. Joints other than the shoulder, such as the knee and hip, can be affected by a condition similar to MSS, sometimes in the same individual with shoulder involvement. In contrast to primary OA, lateral tibiofemoral compartment involvement is common in BCP-associated destructive knee arthropathy. Concurrent CPPD, biomechanical abnormalities, chronic renal failure, and neuropathic factors appear to be predisposing factors. A kindred with familial OA and apparent Milwaukee shoulder-knee syndrome had an unusual type of degenerative joint disease with both intra-articular and periarticular calcifications.[106]

Aging itself is a factor in articular cartilage BCP crystal deposition.[107] Multiple studies of synovial fluids and cartilage specimens from OA, including recent work that has taken advantage of high-resolution means for BCP crystal detection,[108] have suggested that deposition of intra-articular BCP crystalline material, including HA in the pericellular matrix of chondrocytes and the capacity of joint cartilages to form such deposits, are intimately linked with OA, as well as increased chondrocyte hypertrophy and severity of OA.[92,109-111] One limitation of some of these studies is that cartilages were fixed before analysis, and calcifications can develop as a fixation artifact. However, unequivocally, cartilage and synovial fluid BCP crystals, frequently in conjunction with CPP crystals, are commonly detectable in advanced disease of the knee at the time of total joint replacement for OA.[92,111] Traffic of crystals from articular cartilage to synovium can promote calcific synovial crystal deposits at or just beneath the synovial surface, and synovium-derived rice bodies can give rise to BCP crystal deposits released into the joint space.[112]

Collectively, the abundance of HA and CPP crystals in OA joints is likely to be significant under many clinical circumstances because HA and CPP crystal-induced synovial proliferation, cytotoxic effects on chondrocytes, and synovial and chondrocyte MMP expression have the potential to promote OA progression.[111] Better surveys of joint tissues, with advanced methods for detection of BCP crystals[111,113,114] in particular, will be necessary to improve understanding of clinical impact of these calcific crystals on OA.

## DIAGNOSIS AND DIAGNOSTIC TESTS

### KEY POINTS

**The presence of radiographic evidence for chondrocalcinosis is a common finding in elderly and does not necessarily indicate that the patient's symptomatic articular problem is the result of CPPD, which is often asymptomatic.**

**The use of compensated polarized light microscopy is essential to confirm the presence of positively birefringent CPP crystals, although it should be noted that some CPP crystals are nonbirefringent.**

**High-resolution ultrasound of the affected joint is a useful and, in many cases, more sensitive approach than plain radiography in screening for CPPD.**

## Differential Diagnosis

CPPD can imitate a number of other conditions, and vice versa (see Table 96-3), which mandates attention to fulfillment of EULAR[1] and other diagnostic criteria for CPPD (see Table 96-1), with careful adherence to a diagnostic algorithm (Figure 96-8). Conversely, it is important to note that the presence of radiographic evidence for chondrocalcinosis is a common finding in the elderly and does

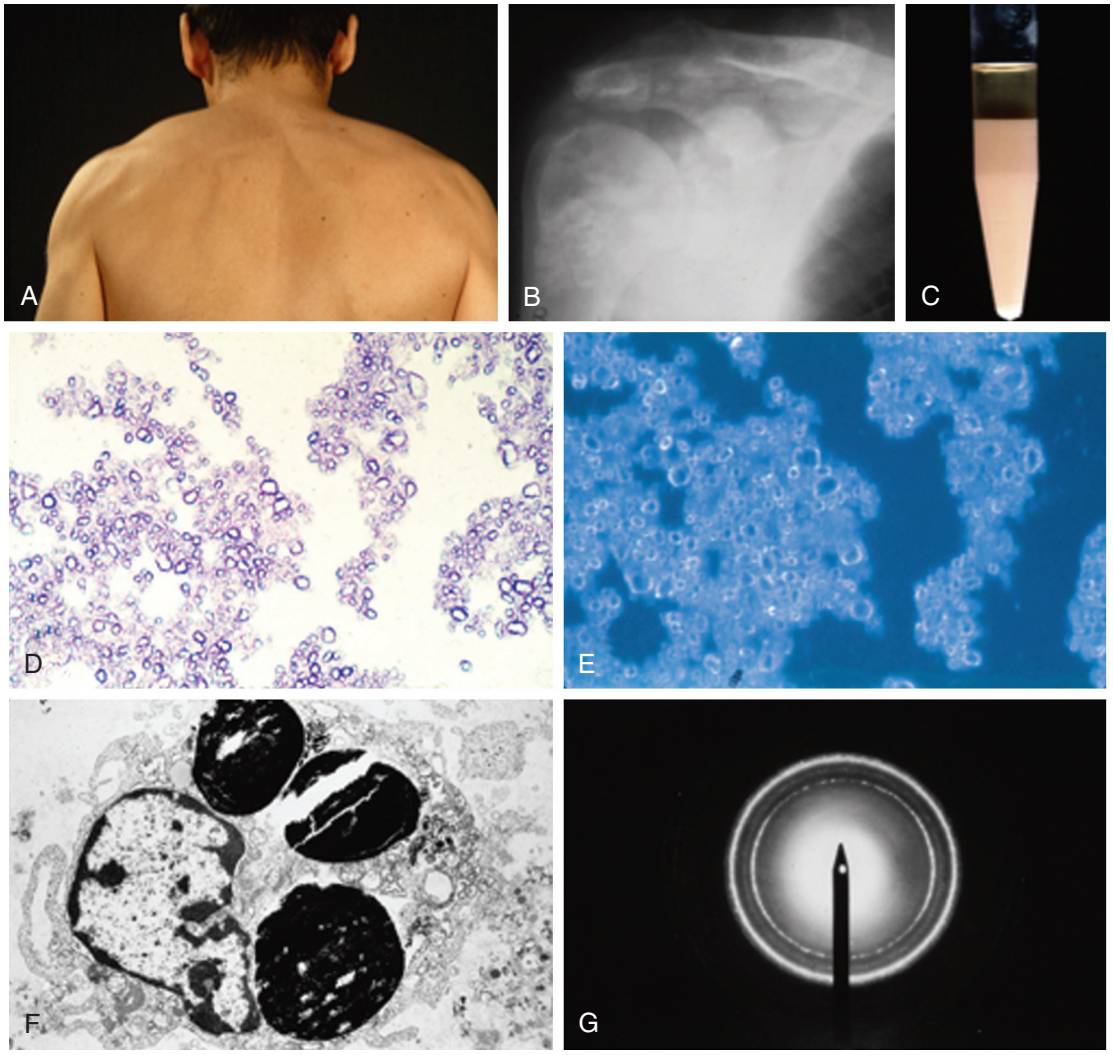

**Figure 96-7** Hydroxyapatite crystal-associated calcific bursitis of the shoulder in a patient with chronic renal failure and secondary hyperparathyroidism. **A,** Chronic soft tissue swelling involving the right shoulder caused by calcific right shoulder subacromial bursitis in a middle-aged male with a history of chronic renal failure on hemodialysis. Note the convex contour of the right shoulder compared with the left. **B,** Radiograph showing extensive calcification both within the rotator cuff and the expanded subacromial bursa surrounding the right shoulder joint. Incidental note is made of the resorption of the distal end of the clavicle consistent with the secondary hyperparathyroidism in this patient. **C,** Subacromial bursa fluid from the right shoulder. Note the milk-white appearance, with chalky sediment of the particulate material in the fluid after centrifugation consistent with crystal deposition disease. **D,** Microscopic appearance of bursa fluid aggregates of basic calcium phosphate crystals in the absence of special stains. The particles are irregular but have approximately spherical profiles. (Unstained magnification ×250.) **E,** Appearance of the bursa fluid under polarized light microscopy. Importantly, the aggregated particles of basic calcium phosphate crystals demonstrate edge birefringence but do not display intrusive birefringence, as seen in the figure. (Unstained magnification ×250.) **F,** Electron photomicrograph of a mononuclear phagocyte from this bursa fluid that contained phagocytosed electron dense *(dark black)* spherical aggregates of crystals of the basic calcium phosphate hydroxyapatite in three phagolysosomes oriented vertically to the right of the nucleus. Hundreds of tiny needle-shaped hydroxyapatite crystals are clumped in each of these dense aggregates. For perspective, the size of the mononuclear phagocyte is approximately 20 μm, and an individual (nonaggregated) hydroxyapatite crystal is approximately 0.04 × 0.01 × 0.01 μm in size. (Transmission electron microscopy, magnification ×1000.) **G,** Electron diffraction pattern of hydroxyapatite crystal aggregates. The diffraction rings are indicative of a powder pattern (i.e., small crystals). The position of the bright rings with d-spacings = 3.44 and 2.81 are characteristic of hydroxyapatite (calcium apatite). *(Courtesy Dr. Ken Pritzker, Mount Sinai Hospital Pathology Department, University of Toronto, Ontario, Canada.)*

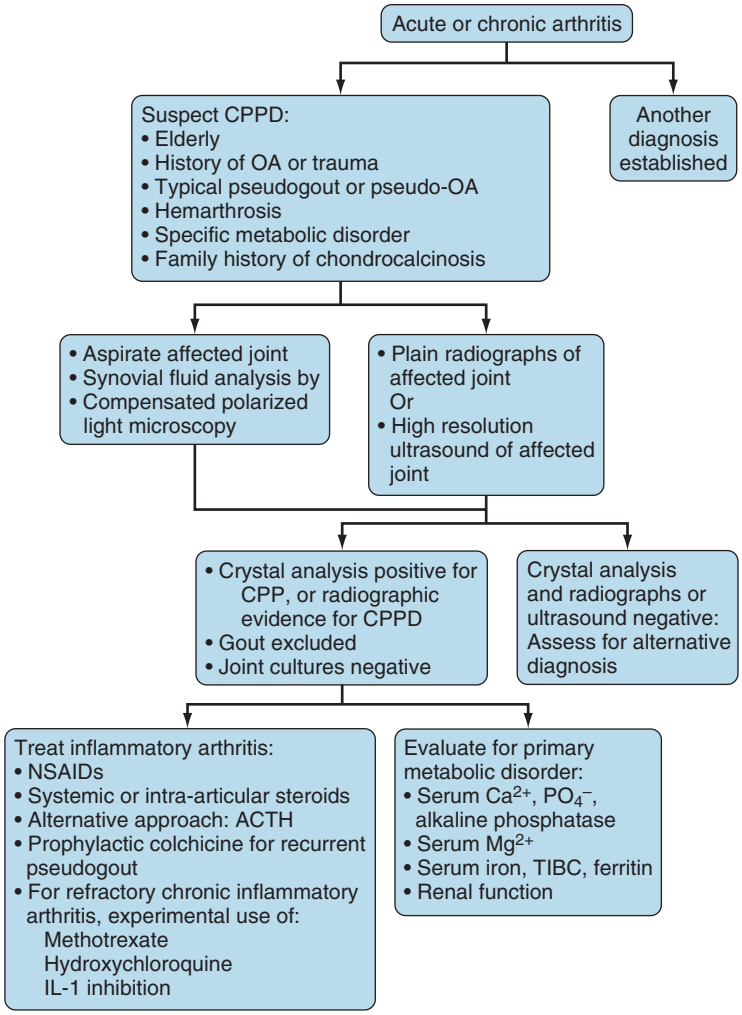

**Figure 96-8** Algorithm for diagnosis, evaluation, and treatment of CPPD. The algorithm is discussed in detail in the text. Treatment options are in line with those recently advanced by the European League Against Rheumatism. ACTH, Adrenocorticotropic hormone; IL, interleukin; NSAIDs, nonsteroidal anti-inflammatory drugs; OA, osteoarthritis; TIBC, total iron binding capacity. *(From Guerne P-A, Terkeltaub R: Calcium pyrophosphate dihydrate crystal deposition: epidemiology, clinical features, diagnosis, and treatment. In Terkeltaub R, editor:* Gout and other crystal arthropathies*, Philadelphia, 2011, Elsevier.)*

not necessarily indicate that the patient's symptomatic articular problem is the result of CPPD, which is often asymptomatic.

The demonstrable presence of CPP crystals in synovial fluid or in tissues by using compensated polarized light microscopy (as discussed earlier for gout vs. pseudogout) is definitive evidence for CPPD.[1] Although weakly birefringent relative to urate crystals and often rhomboid in shape, CPP crystals can be rod shaped and intra-cellular, thereby resembling urate crystals. Thus, the use of compensated polarized light microscopy is essential to confirm the presence of positively birefringent CPP crystals, although it should be noted that some CPP crystals are nonbirefringent.[115] The appearance and number of CPP crystals can change with storage. Therefore, clinicians should examine relatively fresh specimens collected in vials free of calcium-chelating anti-coagulants such as ethylenediaminetetraacetic acid (EDTA).

The ability of pseudogout to mimic septic arthritis (pseudoseptic arthritis) and vice versa underscores the diagnostic importance of arthrocentesis with appropriate synovial fluid crystal analysis and, in many instances, concomitant exclusion of joint infection. Significantly, crystal deposits can be "enzymatically strip-mined" by inflammation associated with joint sepsis. Hence, CPP (as well as other crystals) may be observed extra-cellularly and intra-cellularly in the synovial fluid of an infected joint.

Diagnosis of CPPD in a patient younger than 55 years, particularly if CPPD is widespread, should prompt differential diagnostic consideration of a primary metabolic or familial disorder (see Table 96-2). In the elderly, presentation of CPPD as diffuse pain and fever of unknown origin can mimic infection, polymyalgia rheumatica, and RA. A false-positive rheumatoid factor (RF) test is common in the elderly (≥30% positivity). Thus, patients with pseudorheumatoid arthritis CPPD are often RF seropositive.

## Differential Diagnostic Considerations for Basic Calcium Phosphate Crystal Deposition

BCP crystals may be detected as nonbirefringent globular clumps within leukocytes in some synovial and bursal fluids

(see Figure 96-7), and BCP crystal clumps stain with the calcium-binding dye alizarin red S under light microscopy. CPP crystals can also be detected by using alizarin red S, but they stain more weakly than BCP crystals. Relative paucity of osteophytes (so-called *atrophic degenerative arthritis*) on plain radiographs and the sizeable glenohumeral joint effusions with abundant synovial fluid BCP crystalline material associated with MSS help distinguish MSS from primary OA of the glenohumeral joint. However, destructive neuropathic shoulder arthropathy resulting from syringomyelia or alcoholism sometimes merits consideration in the differential diagnosis of MSS (see Chapter 46). Oxalate crystal deposition arthropathy can be a major differential diagnostic consideration with BCP-associated arthritis and periarticular calcifications in dialysis-dependent renal failure.

## Plain Radiographs

Chronic arthritis in CPPD has several clinical and plain radiographic features that help to differentiate it from OA. These features include involvement at sites uncommon for primary OA, such as the wrist, metacarpophalangeal joints, elbow, or shoulder, as well as radiographic heavy punctate and linear calcifications in fibrocartilages, articular (hyaline) cartilages, and joint capsules, especially if bilaterally symmetric (see Figures 96-5 and 96-6). It should be noted that faint or atypical calcifications may be caused by BCP-related vascular calcifications. Deposition of nonpathologic dicalcium phosphate dihydrate (DCPD) ($CaHPO_4{\cdot}2H_2O$, calcium-to-phosphate ratio of 1) ("brushite") crystals has been thought to cause some atypical calcifications, but brushite crystals can arise as an artifact of acid preparation of calcified tissue for pathologic analyses.

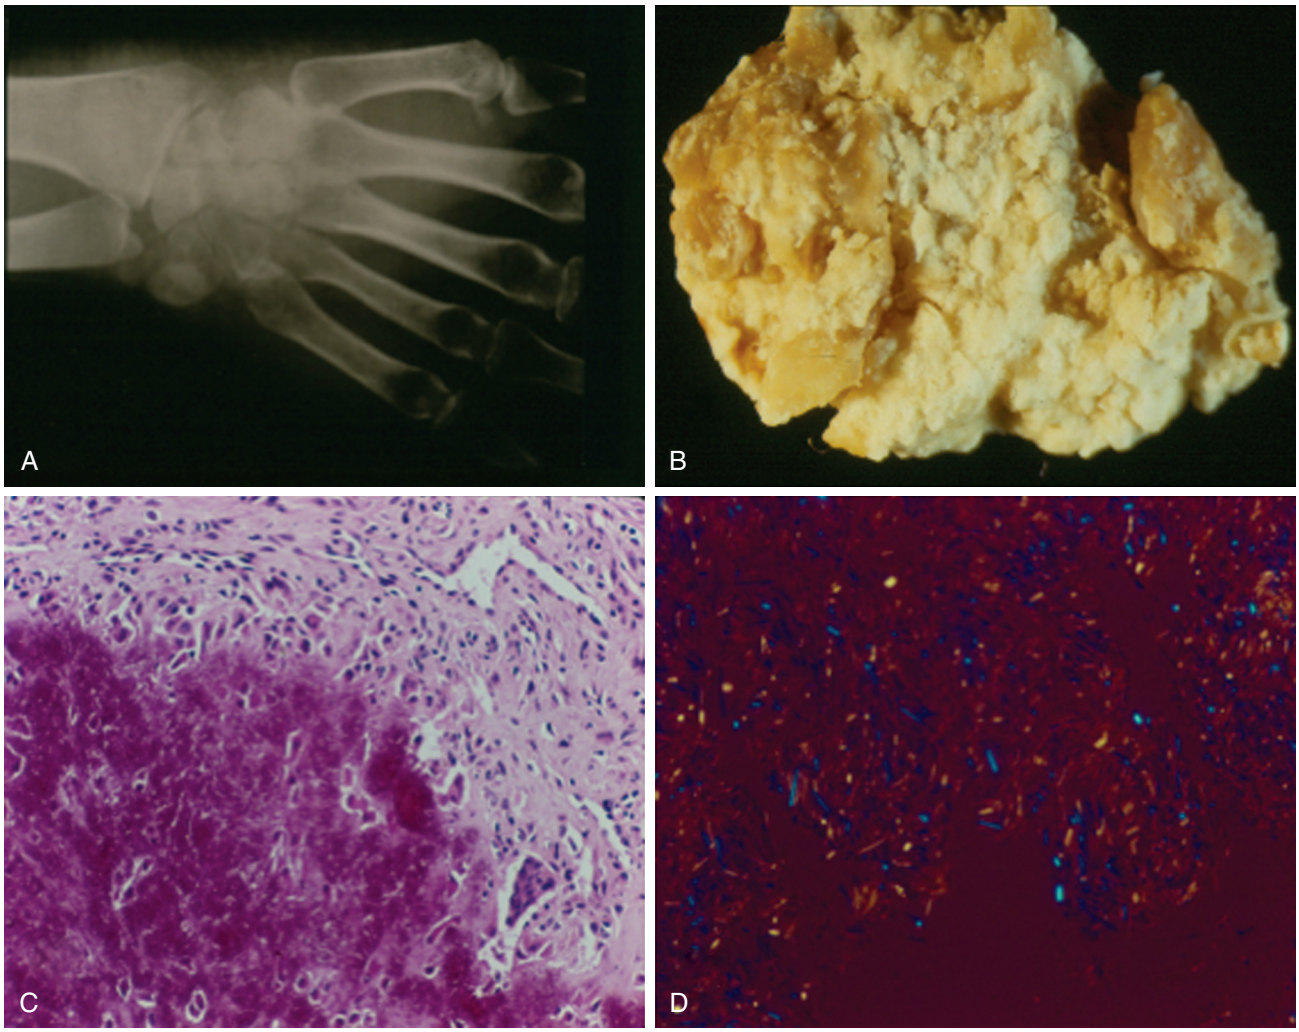
CPP crystal deposits often appear as broad linear streaks or linear "chunks" in articular hyaline and fibrocartilages on plain radiographs, whereas BCP crystal deposits in articular cartilage require high-resolution radiography for detection. Only a pattern of "atrophic" degenerative arthritis without osteophytes and variable subchondral bone thickening may be seen on plain radiographs of BCP arthritis in the shoulder and other large joints.

Patients with arthritis in whom CPPD is part of the differential diagnosis are typically screened first by plain radiography, which remains far more accessible than articular ultrasound imaging. The knee is the most common site of radiographic chondrocalcinosis, but 42% of the CPPD cases in one study had no knee involvement detectable by plain radiograph.[9] Hence, joint-specific screening is advisable for CPPD, rather than the use of knee radiographs to attempt to diagnose CPPD at sites other than the knee. The diagnosis of CPPD in one joint may warrant a search for CPPD at other sites, to assess whether the CPPD is monoarticular or part of polyarticular disease. In this circumstance, the yield is substantial for an anteroposterior (AP) view of each knee, an AP view of the pelvis (to detect symphysis pubis involvement), and posteroanterior (PA) views of both hands that include visualization of both wrists.

Calcific deposits may or may not be detectable by radiography screening of some areas in CPPD. In this circumstance, radiographic evidence other than chondrocalcinosis may point to the correct diagnosis.[116] For example, radiographic findings suggestive of CPPD, as opposed to primary OA, include radiocarpal or marked patellofemoral joint space narrowing, especially if isolated (such as the patella "wrapped around" the femur), as well as scaphoid-lunate widening and femoral cortical erosion superior to the patella. Severe progressive degeneration in the knee with subchondral bony collapse (microfractures) and fragmentation with formation of intra-articular radiodense bodies is a feature of CPPD manifesting as a "pseudoneuropathic" joint.

CPPD involving the metacarpophalangeal joints can be distinguished radiographically from RA by metacarpal squaring associated with "beaklike" osteophytes and subchondral cyst formation. Tendon calcifications (e.g., Achilles, triceps, and obturator tendons) are a valuable differential diagnostic feature of CPPD. Osteophyte formation is more variable with CPPD than with OA. Clearly, radiographic findings often fail to correlate with pathologic and clinical manifestations in CPPD.

## High-Resolution Ultrasound and Advanced Imaging



High-resolution ultrasound imaging can detect aggregated BCP-related calcifications outside of joint cartilages including in the rotator cuff of the shoulder. In addition, ultrasound detects CPP crystal deposits with high sensitivity within articular cartilage, and in plantar fascia and the Achilles and other tendons joints.[117-121] Moreover, ultrasound has higher sensitivity than plain radiography for CPPD.[119,122-124] High-resolution ultrasound for imaging CPP crystals also has high specificity, since results correlate well with positive results for synovial fluid analysis.[119] Preliminary criteria proposed for CPPD calcifications by ultrasound are summarized in Table 96-4 and Figure 96-9 (see also supplemental Figure 96-4 on ExpertConsult.com) illustrate characteristic ultrasound features of CPP crystal deposits.

Ultrasound is expedient, inexpensive, does not use irradiation, and can also assess for joint inflammation and

**Table 96-4** Preliminary Criteria for CPPD Crystal Deposition Diagnosis by High-Resolution Ultrasound

| |
|---|
| All CPPD deposits are hyperechoic and appear as one of the following patterns: |
| Thin hyperechoic bands, parallel to the surface of the hyaline cartilage (frequently observed in the knee)<br>A "punctate" pattern, composed of several thin hyperechoic spots, more common in fibrous cartilage and in tendons<br>Homogeneous hyperechoic nodular or oval deposits localized in bursae and articular recesses (frequently mobile) |
| CPPD crystal deposit calcifications always have a sparkling appearance and create posterior shadowing only when they reach dimensions of greater than 10 mm. In contrast, calcifications that present a hypoechoic appearance with posterior shadowing even at an early stage (2-3 mm in diameter) are considered as crystalline deposits of another nature, most commonly because of basic calcium phosphate crystal deposition disease. |

alternative diagnoses and guide therapeutic joint aspiration in CPPD. EULAR has endorsed ultrasound as a useful modality in CPPD diagnosis.[1] However, limitations of ultrasound include difficulty in visualizing crystal deposits in deep recesses of the joint space and the operator-dependence of the approach. Further validation studies for distinct joints and periarticular tissues are necessary before the relative priorities for roles of ultrasound and radiography in the CPPD diagnostic algorithm can be recommended. Ultrasound imaging appears particularly specific for detection of CPP crystal deposition in fibrocartilages (e.g., triangular fibrocartilage of the wrist and the mid zones of articular hyaline cartilages (see Figure 96-9). However, enthesopathies other than CPPD can also give rise to calcification of tendons and plantar fascia, and the diagnostic value for CPPD of ultrasound detection of calcification in plantar fascia and Achilles tendon[125] is not yet clear.

A recent systematic review of 27 research papers, and meta-analysis of 13 of them, on the subject of ultrasound for CPPD concluded that there were significant variations in sensitivity between joints. Sensitivity was between 0.34 (95% CI 0.02-0.65) to 0.87 (95% CI 0.76-0.99), with specificity between 0.84 (95% CI 0.52-1.00) to 1.00 (95% CI 0.99-1.00).[126]

Ultrasound, without use of synovial fluid analysis in the differential diagnosis of acute arthritis, runs the risk of missing other conditions such as infectious arthritis, which can be superimposed upon CPPD or mimic acute CPP arthritis clinically.[121] Gout can generally be differentiated, particularly because redundant hyperechoic contouring ("double contour sign") of the hyaline cartilage surface is seen more in gout, whereas CPP crystal deposition disease is typically visualized within hyaline articular cartilage.[118,120-122]

Dual-energy CT has not been studied in detail for CPPD detection, but it can specifically distinguish deposits of urate crystals from those of calcium-containing crystals.[127] MRI is not yet a reliable approach for detecting CPPD because of a lack of mobile protons in CPP crystals, and nonenhanced MRI is less sensitive in detecting knee meniscal fibrocartilage calcification than hyaline cartilage calcification.[128]

### Laboratory Diagnostic Tests

Conventional radiography or ultrasound is usually the first method to evaluate patients with suspected CPPD, but thorough laboratory evaluation of the newly diagnosed patient with CPPD routinely includes serum levels of calcium, phosphorus, magnesium, alkaline phosphatase, ferritin, iron, and total iron-binding capacity (see Figure 96-8).

Specialized techniques beyond alizarin red S staining such as radiography diffraction, Raman spectroscopy, Fourier transform infrared spectroscopy, atomic force microscopy, or transmission electron microscopy showing electron-dense clumps of needle-like crystals may be necessary to confirm BCP crystal deposition (see Figure 96-7).[108]

Raman spectroscopic identification of CPP (and urate) crystals appears to be a viable approach for rapid point of care diagnosis of acute CPP arthritis and differentiation from acute gout. In a recent study, Raman spectroscopy and compensated polarized light microscopy analyses were in agreement in 89.7% of samples, and in diagnosing acute CPP arthritis, the Kappa coefficient for agreement between the 2 methods was 0.61 (95% CI 0.42-0.81), though below the Kappa coefficient of 0.84 (95% CI 0.75-0.94) for diagnosing acute gout.[128a]

Primary symptomatic OA is commonly linked with secondary CPPD, and once positive for CPP crystals, OA synovial fluids typically remain positive for CPPD.[124] Cytocentrifugation increases the sensitivity of detection of rare CPP crystals,[129] illustrated by a study in which approximately 75% to 78% of synovial fluid samples (of patients with gout and OA) had both urate and CPP crystals.[130] Under conditions in which synovial fluid specimens are not fresh (or stored at 4° C for analysis after significant delay), Gram stain and Diff-Quik (Microptic, Barcelona, Spain) staining methods for crystal analysis in synovial fluids can provide information beyond that from compensated polarized light microscopy. Demonstration of CPP crystals in articular tissues (see Figure 96-3) can be difficult in specimens stained with hematoxylin and eosin because the acidity of hematoxylin solutions promotes decalcification. However, the decalcifying effect of hematoxylin can be diminished by limiting the staining period with Mayer's hematoxylin to 3 minutes. Studies on Raman spectroscopy for standardized laboratory diagnosis of CPP, BCP, and urate crystals in joint fluid particularly illustrate the potential for development of "point and shoot" diagnostics of crystal arthropathy,[131] which could improve on current inconsistences of crystal arthropathy diagnosis in many medical laboratories.

## TREATMENT

**KEY POINTS**

**CPPD treatment involves alleviation and prophylaxis of acute arthritic attacks, but therapy to lessen chronic and anatomically progressive sequelae of crystal deposition is not well developed for CPPD.**

**The approach to pseudogout treatment is similar to that for acute gout.**

### CPPD

A treatment algorithm is presented at the bottom of Figure 96-8 that is consonant with EULAR guidelines.[132] As in gout (see Chapter 95), therapeutic approaches to patients with CPPD involve treatment and prophylaxis of acute arthritic attacks.[132,133] Effective therapies to lessen CPP crystal deposition, and chronic and anatomically progressive sequelae of CPP crystal deposition, have not been developed for idiopathic or familial CPPD (Table 96-5). Moreover, it is not clear that appropriate treatment of hemochromatosis, hyperparathyroidism, and hypomagnesemia prevent or limit CPP crystal deposition and associated inflammation and cartilage degeneration, likely because the ability to detect chondrocalcinosis by radiography is usually indicative of advanced crystal deposition disease.

Episodes of pseudogout generally respond to NSAIDs (including cyclooxygenase-2 inhibitors) and/or intra-articular steroids,[132] although sometimes more slowly than in gout. Systemic glucocorticosteroids or adrenocorticotropic hormone [132,134] usually given as described for acute

**Table 96-5** Therapeutics for Calcium Pyrophosphate Dihydrate Crystal Deposition Disease (CPPD)

| |
|---|
| **Proven Benefits** |
| NSAIDs or COX-2 inhibitors |
| Intra-articular corticosteroids |
| Systemic corticosteroids |
| ACTH |
| Prophylactic low-dose colchicine |
| **Possible Benefits Already Observed Clinically** |
| Methotrexate for refractory chronic inflammation and recurrent pseudogout |
| Oral magnesium (for patients with hypomagnesemia) |
| **Theoretic Benefits** |
| Hydroxychloroquine for refractory chronic inflammation |
| Phosphocitrate |
| Caspase-1 or IL-1 antagonism for CPPD crystal-induced inflammation |
| TLR2 antagonism for CPPD-associated degenerative arthropathy |
| Oral calcium supplementation to suppress PTH levels |
| ANKH anion channel blockade (probenecid) |
| ENPP1 inhibition |
| TG2 inhibition |
| Polyphosphates |
| Promotion of crystal dissolution by alkaline phosphatase or polyamines |

ACTH, Adrenocorticotropic hormone; COX-2, cyclooxygenase-2; IL, interleukin; ENPP1, ecto-nucleotide pyrophosphate phosphodiesterase 1; NSAIDs, nonsteroidal anti-inflammatory drugs; PTH, parathyroid hormone; TG2, transglutaminase 2; TLR2, Toll-like receptor 2.

**Table 96-6** Therapeutics for Articular and Periarticular Basic Calcium Phosphate (BCP) Crystal Deposition

|---|
| **Proven Benefits** |
| NSAIDs or selective COX-2 inhibitors |
| Local corticosteroid injection |
| Local irrigation |
| High-frequency therapeutic ultrasound to degrade BCP crystal deposits |
| **Theoretic Benefits** |
| Phosphocitrate |
| Modulators of ANKH (e.g., probenecid) or ENPP1 |

COX-2, Cyclooxygenase-2; ENPP1, ectonucleotide pyrophosphatase/phosphodiesterase 1; NSAIDs, nonsteroidal anti-inflammatory drugs.

gout (see Chapter 95), appear effective in most cases of acute pseudogout. However, rebound arthritis after tapering systemic glucocorticosteroids in CPPD could be mediated by glucocorticosteroid induction of NLRP3 in macrophage.[135]

The response to colchicine is less consistent than that usually seen in acute gout. However, pseudogout episodes can be diminished in frequency by low-dose daily colchicine prophylaxis, as for gouty arthritis.[132,133] The self-limited nature of most acute pseudogout attacks in the knee can sometimes be accelerated by simple arthrocentesis and thorough drainage of the joint effusion, but there are currently no data for measures such as tidal irrigation in CPPD, unlike the case for MSS.[136,137]

Hydroxychloroquine[133] has been suggested to be of some benefit to patients with refractory chronic polyarticular CPPD and to reduce flares of pseudogout, and it has theoretic benefits by potentially stabilizing phagolysosomes to suppress NLRP3 inflammasome activation in response to crystal uptake.[138] Methotrexate was found promising to patients with refractory chronic polyarticular CPPD and to reduce flares of pseudogout, although in an exploratory study limited to five consecutive patients, and with patients prior to methotrexate as their own controls.[139] Though methotrexate does appear effective in some with chronic inflammatory CPPD arthritis, it clearly it has not been adequately studied to date.[139a] IL-1 antagonism (e.g., with off-label use of anakinra) has had anecdotal success,[140,141] whereas breakthrough pseudogout has been reported during TNF antagonist therapy.[142] Collectively, at this time there is insufficient evidence for hydroxychloroquine, methotrexate, and IL-1 antagonism as standard therapies for refractory inflammation in CPPD.

Only limited evidence suggests that OA patients with cartilage calcification respond to arthroscopic irrigation and daily low-dose colchicine; further substantiation is necessary. There is currently no evidence to support arthroscopic débridement as a treatment modality for CPPD deposition disease. There is insufficient evidence for beneficial effects of intra-articular hyaluronan therapy in CPPD of the knee, and risks of precipitating pseudogout appear significant with this treatment modality.

## Basic Calcium Phosphate Crystal Arthropathies

NSAIDs and local glucocorticoid injection (Table 96-6) are effective treatment options for BCP crystal-associated calcific tendinitis and subacromial bursitis (see Chapter 46). BCP crystal–associated inflammation of the rotator cuff and subacromial bursa of the shoulder can be successfully treated by using needle aspiration, irrigation, and steroid injections. Ultrasound-guided techniques, which promote resorption of rotator cuff and bursal calcifications, can enhance the success of such approaches.[133] Tidal irrigation may be of benefit for symptoms and function in MSS.[133]

## Future Directions in Treatment

Simple measures such as prevention and detection of hypomagnesemia and occult hyperparathyroidism merit long-term investigation at the population level. The potential to develop therapies for both CPPD and BCP crystal–associated arthropathies based on new molecular targets has been elevated by identification of ANKH and ENPP1 as specific molecular mediators of cartilage calcification. Intriguingly, the anion transport inhibitor probenecid suppresses *ANKH*-induced and TGF-β–induced increases in extra-cellular $PP_i$ in vitro.[38] Prevention of CPP crystal deposition by polyphosphates or promotion of CPPD dissolution by depot alkaline phosphatase and by pyrophosphatase activation-promoting polyamines could provide alternative therapeutic approaches.[143] However, incomplete CPP crystal dissolution by intra-articular lavage of patients with chondrocalcinosis of the knees with disodium EDTA and

magnesium ions in the past was a therapeutic failure, in that insignificant amounts of CPP crystals were removed, and all postlavage attacks of pseudogout mediated by crystal shedding developed in all patients.

The $PP_i$ analogue phosphocitrate, a natural compound in mammalian mitochondria and in the urinary tract, is a potent inhibitor of HA crystal formation.[144] Phosphocitrate inhibits nitric oxide–induced calcification of cartilage and also inhibits both HA and CPPD crystal–associated cell stimulation including induction of MMP-3 in fibroblasts. Systemic phosphocitrate treatment suppresses ankylosing ossification in murine progressive ankylosis of *ank/ank* mice. Moreover, an analogue of phosphocitrate (CaNaPC) decreased both the abundant meniscal cartilage HA deposition and the continuous progression of OA in the Hartley guinea pig model of spontaneous knee OA.[145] The CaNaPC treatment did not exert therapeutic effects in a rabbit knee hemimeniscectomy model of OA in which there was an absence of intra-articular calcification.[145] Such results suggest that phosphocitrate acts on calcification-mediated mechanisms of dysregulation of joint biomechanics and cartilage degeneration without exerting nonspecific chondroprotective effects. Further clinical development of phosphocitrate would be of interest but has been slowed in part by low bioavailability unless given parenterally.[144]

The use of bisphosphonates as $PP_i$ analogues can be beneficial in some cases of soft tissue calcification with HA. Lastly, the identified roles of TLR2 in chondrocyte responsiveness to CPP crystals,[77] of TLR4 in hydroxyapatite crystal–induced inflammatory responses,[146] and of NLRP3 inflammasome-mediated caspase-1 activation and IL-1β processing in CPP and BCP crystal–induced inflammation[74,75] suggest certain mediators of innate immunity including TLR2, TLR4, caspase-1, and IL-1β to be potential therapeutic targets for human forms of CPPD and hydroxyapatite crystal-driven inflammation and connective tissue destruction.

## OUTCOME

### KEY POINTS

- It is not clear whether the presence of CPP or BCP crystals in primary knee OA play a net role in promoting disease progression and more frequent knee replacement surgery, despite the fact that CPP and BCP crystals are frequently found in OA knee tissues at the time of total joint arthroplasty.
- There is no clear correlation between the extent of calcification and progression of primary CPPD arthropathy.
- The outcome of total knee arthroplasty does not appear to be significantly altered by pre-existing CPPD.

Mean radiographic scores have been found to directly correlate with the presence of calcium-containing crystals in OA in patients at the time of total joint arthroplasty.[92] However, degenerative cartilage disease associated with sporadic CPPD may be less destructive than that observed in primary OA. For example, limited prospective analysis of knee CPPD has suggested that radiographic worsening of degenerative arthritis was slow to progress. Typically, changes in radiographic extent of chondrocalcinosis are observed over time, but there is no clear correlation between the extent of calcification and progression of CPPD arthropathy.

In the Boston OA Knee Study (BOKS), and in the Health, Aging, and Body Composition (Health ABC) Study,[147] the relationship between chondrocalcinosis and the progression of knee OA was prospectively evaluated longitudinally by using MRI. In BOKS, knees with chondrocalcinosis had a decreased risk of cartilage loss compared with knees without chondrocalcinosis, and there was no difference in risk in Health ABC. Stratification by the presence of intact or damaged knee menisci produced comparable results within each cohort. In a Thai study, CPPD was identified radiographically and/or by synovial fluid analysis in 52.9% of 102 patients undergoing total knee arthroplasty.[148] Patients with and without CPPD did not differ in difficulties in performing daily activities or treatment, and those with CPPD did not undergo knee arthroplasty at an earlier age than those without CPPD. The outcome of total knee arthroplasty also does not appear to be significantly altered by pre-existing CPPD,[149] unless there is robust synovitis.[150]

In the setting of OA, processes leading to cartilage matrix calcification by CPP and BCP crystals appear to be biomarkers of both aging and secondary consequences of advanced cartilage pathology. The net role of CPP and BCP crystals in synovitis and chondrocyte pro-catabolic processes remains unclear in the progression of primary OA. Moreover, the dysregulated cartilage matrix repair that generates secondary CPPD in primary OA may be a biomarker of processes that slow cartilage tissue failure in at least some patients.

## CONCLUSION

CPPD is particularly common in aging, and is also linked with OA and cartilage matrix degeneration and abnormalities in chondrocyte differentiation and $PP_i$ metabolism, some of which are hereditary via ANKH dysregulation. Articular cartilage BCP crystal deposition is strongly linked with OA. Inflammatory responses to both CPP and BCP crystals are mediated by NLRP3 inflammasome activation and IL-1β release. CPPD can mimic multiple conditions, including gout, infectious arthritis, primary osteoarthritis, RA, and polymyalgia rheumatica. Cervical spine CPPD is common, and can be destructive. Major diagnostic approaches to CPPD include plain radiography and high-resolution ultrasound, in addition to the gold standard of synovial fluid crystal analysis with compensated polarized light microscopy. Treatment of acute CPPD arthritis is similar to that used in gout. Therapy to prevent CPP crystal deposition is not yet developed. Despite the fact that CPP and BCP crystals are frequently found in cartilage and joint fluid in advanced OA, the roles of CPP and BCP crystals in symptoms and disease progression in primary OA remain unclear.

CHAPTER 97

# Familial Autoinflammatory Syndromes

Anna Simon • Jos W.M. Van Der Meer • Joost P.H. Drenth

**KEY POINTS**

- **Autoinflammatory disorders are characterized by recurrent or chronic inflammation without signs of infection or autoimmunity.**
- **Dysregulation of the interleukin (IL)-1β pathway is central to many autoinflammatory syndromes, especially the cryopyrin-associated periodic syndromes, deficiency of the IL-1 receptor antagonist, and familial Mediterranean fever.**
- **A severe complication of longstanding disease is type amyloid A amyloidosis, which often leads to renal failure; the risk of this complication is greatly reduced when patients receive adequate treatment.**
- **In a substantial portion of patients seen with a clear autoinflammatory phenotype, the specific diagnosis can remain elusive.**
- **Because of the central role of IL-1β in many autoinflammatory diseases, a trial of IL-1β inhibiting therapy can be warranted for diagnostic and therapeutic purposes.**

The familial autoinflammatory syndromes, often referred to as *hereditary periodic fever syndromes*, comprise rare hereditary disorders with a common phenotype of lifelong, recurrent inflammatory episodes, characterized by inflammatory symptoms such as fever, abdominal pain, diarrhea, rash, or arthralgia.[1] Between the fever episodes, patients with most of these syndromes generally feel healthy and function normally. Routine laboratory investigations during a fever attack invariably reveal a severe acute phase response with a high erythrocyte sedimentation rate, leukocytosis, and high concentrations of acute phase proteins such as C-reactive protein (CRP) and serum amyloid A (SAA). The inflammatory episodes occur without an obvious trigger, although some patients note a relationship to physical stimuli (e.g., exposure to cold), emotional stress, or the menstrual cycle. The episodes resolve spontaneously in days or weeks. Patients go undiagnosed for years, generating a high level of discouragement and frustration for patients and physicians when no diagnosis is made.[2,3] The term *autoinflammatory*, coined by McDermott and colleagues in 1999,[4] describes the phenotype of recurrent, acute inflammatory responses. It is preferable to the term *autoimmune* in these cases because typical autoimmune phenomena are not found; innate immune defects are generally responsible rather than the adaptive immune system.[5]

Several genetically distinct types of hereditary autoinflammatory syndromes are recognized. Despite the common phenotype described previously, these can often be differentiated clinically by specific characteristics—in particular, mode of inheritance, age of onset, average duration of the fever episodes and the fever-free interval, geographic region of origin of the patient, and occurrence of long-term complications such as amyloidosis or deafness (Table 97-1 and Figure 97-1). A significant number of patients with a periodic fever phenotype still do not fit into this genetically based classification, probably representing additional (genetic) defects that can lead to autoinflammatory disease. Each year, new genetic disorders are characterized. This chapter describes seven well-characterized familial autoinflammatory syndromes in detail.

## DIFFERENTIAL DIAGNOSIS

When a patient has had recurrent fever episodes for more than 2 years, an infection or a malignant disorder is unlikely. The differential diagnosis at that time might include numerous inflammatory disorders, such as juvenile rheumatoid arthritis, adult-onset Still's disease, inflammatory bowel disease, Schnitzler syndrome, and Behçet's disease, in addition to the familial autoinflammatory syndromes (Table 97-2). Because the hereditary syndromes are rare—except for familial Mediterranean fever (FMF) in individuals with a distinct ethnic background—the more common diagnoses should usually be excluded first.

The mainstay of the diagnosis of hereditary autoinflammatory syndromes is clinical assessment, with a detailed medical and family history, and preferably at least one observation of the patient during a fever episode because physical examination of the patient in a period of remission is seldom abnormal. The physician can gain another helpful clue, although not pathognomonic, from knowing the patient's ethnic origin. This clinical assessment often yields enough information to build a differential diagnosis of the specific familial autoinflammatory syndromes (see Table 97-1) to determine the direction of genetic testing (Figure 97-2). A growing number of genetic laboratories now also offer autoinflammatory syndrome gene panels, in which multiple genes are sequenced simultaneously by next-generation sequencing methods. This has great advantages; on the other hand, the finding of low-penetrant mutations or polymorphisms in these genes can lead to diagnostic problems or mistaken overdiagnosis.

When the specific diagnosis remains elusive, a trial treatment with an IL-1 inhibitor (e.g., anakinra) can give a diagnostic clue. A significant proportion of patients who suffer from an autoinflammatory disease "not otherwise specified" respond well to treatment with anakinra. The

authors even use the (temporary) label of "anakinra-responsive disease" for this category in daily practice.

## FAMILIAL MEDITERRANEAN FEVER

### Epidemiology

FMF is the most prevalent disorder among the hereditary autoinflammatory syndromes, with more than 10,000 patients affected worldwide. It occurs primarily in people originating from the Mediterranean basin, including Armenians, Sephardic Jews, Arabs, and Turks. FMF is an autosomal recessively inherited disorder. Most families reported with an apparent autosomal dominant inheritance pattern of FMF[6] represent examples of pseudodominant inheritance because of consanguinity combined with the high carrier frequency of FMF mutations in certain populations[6-8]; however, at least three families studied do seem to show a true dominant inheritance, even after extensive genetic analysis[9,8]

**TABLE 97-2** Differential Diagnosis of Periodic Fever

      ii. Solid tumor (e.g., pheochromocytoma, myxoma, colon carcinoma)
   d. Vascular (e.g., recurrent pulmonary embolism)
   e. Hypothalamic
   f. Psychogenic periodic fever
   g. Factitious or fraudulent

## Etiology

In 1997, two groups independently traced the genetic background of FMF to a hitherto unknown gene on the short arm of chromosome 16, named the Mediterranean fever (*MEFV*) gene.[10,11] At least 80 disease-linked mutations in the *MEFV* gene have been described so far, most of which are clustered in the tenth exon of this gene (for details, see the online mutation database at http://fmf.igh.cnrs.fr/infevers/). Most are missense mutations that produce a single amino acid change in the protein (Figure 97-3). There are five common mutations, accounting for the majority of FMF chromosomes: M694V (occurring in 20% to 65% of cases, depending on the population examined[12]), V726A (in 7% to 35%), M680I, M694I, and E148Q. For the first three mutations mentioned here, a founder effect has been established,[11] pointing to common ancestors at least 2500 years ago. The high frequency of the mutated *MEFV* gene in more than one Middle Eastern population has led to the hypothesis that heterozygous carriers have an as yet unknown advantage, possibly a heightened (inflammatory) resistance to an as yet unidentified endemic pathogen of the Mediterranean basin.[11] In approximately 30% of patients, only one or no mutations in the *MEFV* gene can be detected; the etiology in these patients still needs to be determined.

## Pathogenesis

The *MEFV* gene encodes for a protein of 781 amino acids, known as *pyrin* or *marenostrin*. Pyrin is expressed as a cytoplasmic protein in mature monocytes in association with microtubules[13] but is predominantly found in the nucleus in granulocytes, dendritic cells, and synovial fibroblasts.[14] Pyrin expression is induced by inflammatory mediators such as IFN-α and TNF.[15] The pyrin domain is shared by many proteins involved in apoptosis and inflammation and is a member of the death-domain superfamily that includes death domains, death-effector domains, and caspase-recruitment domains. Pyrin binds to other proteins that contain similar domains, which include the adapter protein "apoptosis-associated speck-like protein with a CARD" (ASC).

The pro-inflammatory cytokine IL-1β is central in the pathogenesis of FMF. This cytokine is expressed as an inactive precursor, which is cleaved by caspase-1 to yield the active IL-1β. Caspase-1 itself first needs to be activated through the interaction with protein complexes called *inflammasomes*. Several inflammasomes have been described. The major inflammasome complex involved in the activation of caspase-1 and IL-1β is the cryopyrin or NLRP3 inflammasome.[16,17] Two hypotheses have been proposed regarding the effect of pyrin on IL-1β processing. The "sequestration hypothesis" holds that pyrin has an inhibitory effect on caspase-1–mediated activation of IL-1β, through its prevention of the formation of the cryopyrin inflammasome by competitive binding of the adapter protein ASC and procaspase-1 and binding caspase-1.[18,19] Under this hypothesis, FMF mutations are thought to interfere with the inhibiting interactions of pyrin, resulting in decreased regulation of IL-1β activation.[19] The second hypothesis suggests that pyrin can form its own specific inflammasome for activation of IL-1β,[20] although not all the components of this proposed complex have been specified so far. The FMF mutations would increase the sensitivity of this putative pyrin inflammasome. Apart from its role in regulation of IL-1β, there is also conflicting evidence for the effect of pyrin on regulation of nuclear factor-κB (NF-κB) or apoptosis, varying from inhibition to stimulation.[1]

## Clinical Features

In approximately 90% of patients with FMF, symptoms start before age 20 years.[21] The inflammatory attacks of FMF usually last 1 to 3 days. The frequency can vary widely; 2 to 4 weeks is the most common interval (see Figure 97-1). Symptoms of serositis (i.e., peritonitis, pleuritis, synovitis) are the main feature of FMF attacks, usually accompanied by fever. Abdominal pain of 1 or 2 days' duration occurs in 95% of patients, varying in severity from severe peritonitis resembling an acute condition in the abdomen to only mild abdominal pain without overt peritonitis.[22] Arthritis (rarely destructive) is often confined to one large joint such as the knee, ankle, or wrist, and may be the only symptom. Chest pain resulting from pleuritis is usually unilateral and associated with a friction rub or transient pleural effusion. Skin involvement occurs in approximately 30% of patients, most often as erysipelas-like skin lesions on the shins or feet (Figure 97-4).[23] Other, more uncommon, symptoms are pericarditis, occurring in less than 1% of patients[24]; acute scrotal swelling and tenderness[25]; aseptic meningitis; and severe protracted myalgia, especially of the legs.

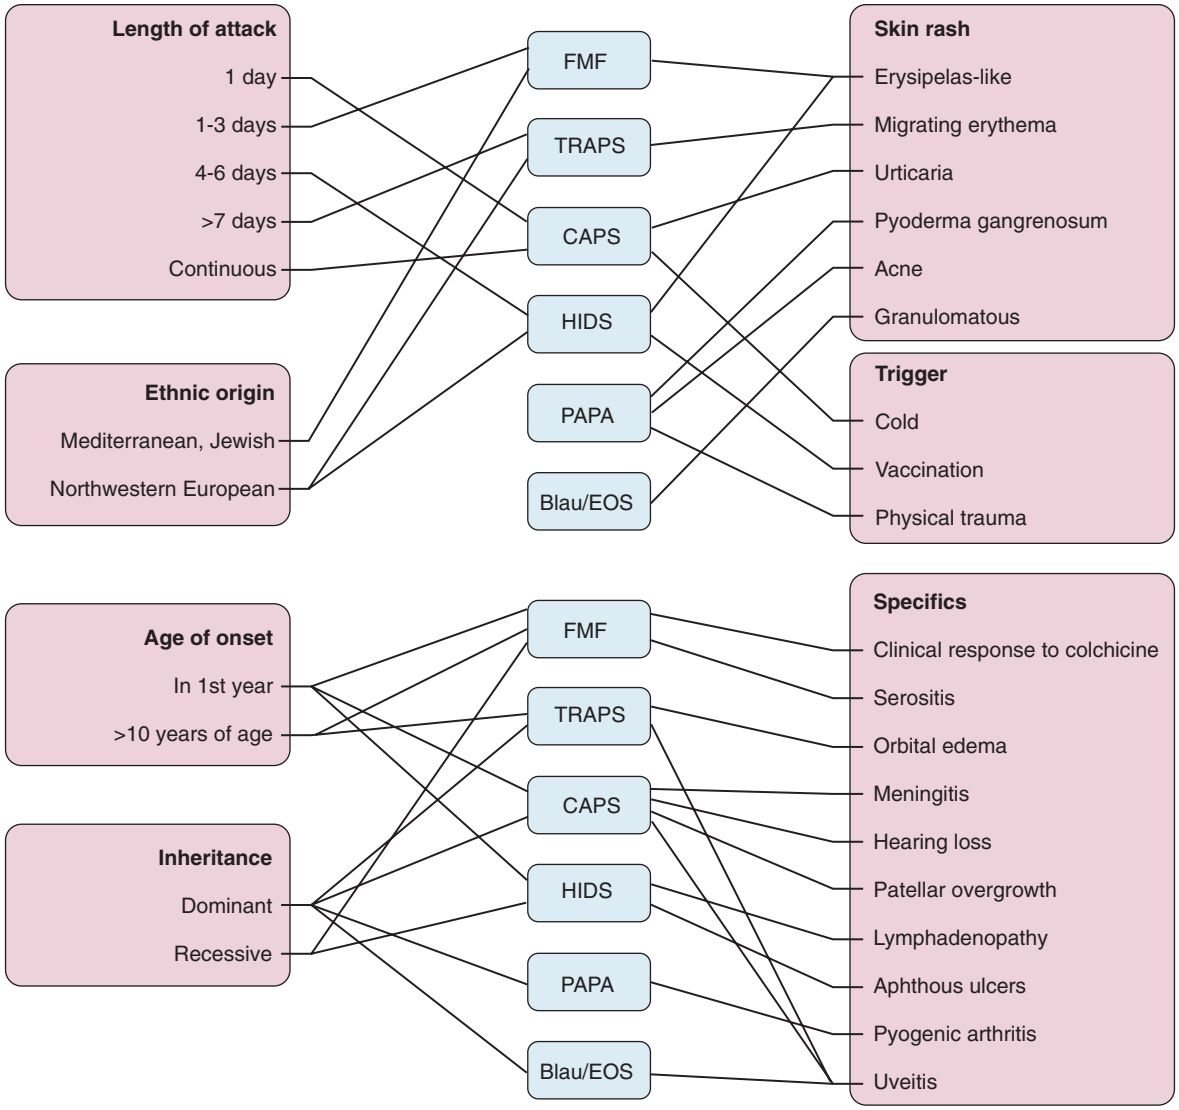

**Figure 97-2** Differential diagnosis of the familial autoinflammatory syndromes. First exclude other, more common causes of fever and inflammation in the patient. When a familial autoinflammatory syndrome seems likely, check the clinical characteristics found in the patient on the right and left of the diagram, and assign one point to each syndrome that is linked to these characteristics by a line (one characteristic could lead to or point to more than one syndrome). The final combined score assigns a rank for the likelihood of the disorders in this patient and offers help in deciding on the correct subsequent diagnostic tests. This algorithm is not evidence based but is solely derived from expert opinion. CAPS, Cryopyrin-associated periodic syndrome; EOS, early-onset sarcoidosis; FMF, familial Mediterranean fever; HIDS, hyper-IgD syndrome; PAPA, pyogenic sterile arthritis, pyoderma gangrenosum, and acne; TRAPS, tumor necrosis factor receptor–associated periodic syndrome.

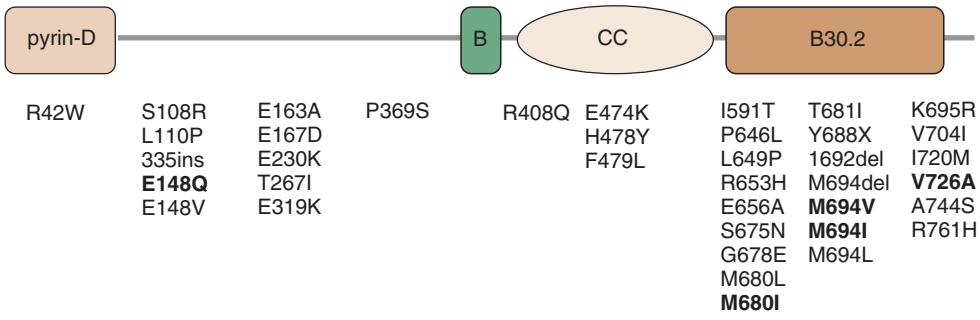

**Figure 97-3** Schematic representation of pyrin (marenostrin) protein, with four conserved domains, including a pyrin domain, a B-box (B), coiled-coil domain (CC), and a B30.2 domain. Indicated are mutations as found in familial Mediterranean fever, with the five most common missense mutations in *boldface* type. For complete listing of all currently known mutations, see INFEVERS website: http://fmf.igh.cnrs.fr/infevers/.

**TABLE 97-3** Diagnostic Criteria for Familial Mediterranean Fever*

| |
|---|
| **Major Criteria** |
| Typical attacks† with peritonitis (generalized) |
| Typical attacks with pleuritis (unilateral) or pericarditis |
| Typical attacks with monoarthritis (hip, knee, ankle) |
| Typical attacks with fever alone |
| Incomplete abdominal attack |
| **Minor Criteria** |
| Incomplete attacks‡ involving chest pain |
| Incomplete attacks involving monoarthritis |
| Exertional leg pain |
| Favorable response to colchicine |

*Requirements for diagnosis of familial Mediterranean fever are ≥1 major criteria or ≥2 minor criteria.

†Typical attacks are defined as recurrent (≥3 of the same type), febrile (≥38° C), and short (lasting between 12 hours and 3 days).

‡Incomplete attacks are defined as painful and recurrent attacks not fulfilling the criteria for a typical attack.

From Livneh A, Langevitz P, Zemer D, et al: Criteria for the diagnosis of familial Mediterranean fever. *Arthritis Rheum* 40:1879–1885, 1997.

## Diagnosis and Diagnostic Tests

FMF is still primarily a clinical diagnosis. There is a set of validated diagnostic criteria with a reported sensitivity and specificity of 96% to 99% (Table 97-3).[26] These criteria were validated in a population with a high prevalence of FMF and a low prevalence of the other autoinflammatory disorders; however, the ethnic origin of the patient needs to be taken into account. In molecular diagnostic testing, genetic laboratories usually screen for the five most common mutations, and rare mutations are missed. *MEFV* mutations occur on both alleles in only 70% of typical cases,[27] whereas in the remaining 30%, only one or no mutation can be detected, even after sequencing. There is also evidence of reduced penetrance. Despite these limitations, molecular testing can be used as a confirmatory test. Whether or not the results are positive, treatment with colchicine is warranted in symptomatic cases of fitting ethnic origin fulfilling the diagnostic criteria.[28,29] No specific biologic marker is available to distinguish an inflammatory FMF attack from an infectious fever or appendicitis. During an inflammatory attack, there is an acute phase response, which includes elevation of SAA, CRP, and plasma fibrinogen and polymorphonuclear leukocytosis. Proteinuria in patients with FMF is highly suggestive of renal amyloidosis.

## Treatment

Colchicine is the first-line treatment for patients with FMF. It prevents inflammatory attacks completely in 60% to 75% of patients, and it significantly reduces the number of attacks in an additional 20% to 30%.[30] The average dose in adults is 1 mg daily but may be increased to 3 mg if no response is seen at the lower dose. This regimen is usually well tolerated; gastrointestinal side effects, including diarrhea and abdominal pain, generally resolve with dose reduction. More serious side effects, such as myopathy, neuropathy, and leukopenia are rare and occur primarily in patients with renal or liver impairment. During a fever attack, oral or intramuscular NSAIDs can be used for pain relief. Glucocorticoids have limited efficacy.

Compliance with colchicine use is important because colchicine prevents amyloidosis. Since the introduction of colchicine therapy, the incidence of amyloidosis in FMF has decreased dramatically, whereas in areas with a high prevalence of FMF where colchicine is not routinely available, such as Armenia, amyloidosis is still common. Colchicine's principal effect at the cellular level is to depolymerize microtubules by interacting with tubulin, inhibiting motility and exostosis of intra-cellular granules. It has a powerful anti-mitotic effect, causing metaphase arrest. It has been speculated, in cases of infertility in patients treated with colchicine, that this medication causes azoospermia. Colchicine does not have a significant adverse effect on sperm production or function, however.[31] Unfounded fear of teratogenic effects of colchicine often wrongly leads to cessation of this drug in young women who want to get pregnant, with a subsequent increased frequency and severity of attacks, which enhances problems with fertility and pregnancy. Colchicine has proven to be safe, even in early pregnancy, and treatment should not be interrupted for this reason.[32,33] It can also be used while breastfeeding.[30]

In approximately 5% to 10% of patients, FMF is refractory to colchicine use. Parenteral colchicine can be used in refractory cases,[34] but can be toxic. Currently, IL-1β inhibitors are more commonly used in colchicine-resistant FMF, as reported in several case reports and retrospective series.[35-40]

## Outcome

Recurrent attacks of peritonitis may lead to intra-abdominal or pelvic adhesions, resulting in complications such as small bowel obstruction. Another serious long-term complication of FMF is amyloid A (AA) amyloidosis. This amyloidosis is primarily found in the kidneys, resulting in renal failure, but can also occur in the gastrointestinal tract, liver, and spleen, and eventually in the heart, testes, and thyroid in late stages. The prevalence of amyloidosis varies, especially depending on the ethnic origin, but it is high in untreated patients. It is common among Sephardic Jews but rare in Ashkenazi Jews.[41]

For a variety of reasons, including peritoneal adhesions and ovulatory dysfunction, subfertility in women is

common.[32] In men, subfertility secondary to azoospermia (sometimes secondary to testicular amyloidosis) or impairment of sperm penetration has been found.[21]

## MEVALONATE KINASE DEFICIENCY (HYPER-IGD SYNDROME)

### Epidemiology

Hyper-IgD syndrome (HIDS), also known as *mevalonate kinase deficiency (MKD)*, is an autosomal recessively inherited disorder, but it is far less prevalent than FMF. Approximately 75% of patients are from Western Europe, and 50% are from the Netherlands and France.[42] Most patients with MKD are of Caucasian origin. These observations can be explained partly by a founder effect.[43] In the Netherlands, the carrier frequency of the most common mevalonate kinase mutation is 1:153.[44] Men and women are equally affected.[42]

### Etiology

MKD is caused by mutations in the gene encoding for the enzyme mevalonate kinase, located on the long arm of chromosome 12.[45-47] Patients are most often compound heterozygotes for two missense mutations (Figure 97-5). Two mutations (V377I and I268T) account for more than 85% of the patients described to date.[42]

The term *variant-type HIDS*, which was proposed for patients with an autoinflammatory disease and high IgD without MVD,[47] has been largely abandoned. Many patients with fever syndromes have a raised IgD, and this subclass is heterogeneous. It seems more useful to designate these patients with "autoinflammatory disease not otherwise specified" to indicate that a more specific diagnosis may still be found in the future.

### Pathogenesis

Mevalonate kinase is part of the isoprenoid pathway; it is the step after 3-hydroxy-3-methyl-glutaryl–coenzyme A (HMG-CoA) reductase, phosphorylating mevalonic acid. The isoprenoid pathway has many diverse end products that include cholesterol, dolichol, and ubiquinone, and it leads to isoprenylation of proteins, with a post-translational modification directing these proteins such as Rho and Ras to the cell membrane.[48]

MKD mutations lead to a constantly diminished activity of mevalonate kinase to approximately 5% to 15% of normal levels, and these levels decrease further during a fever attack.[49] Because of this reduced enzyme activity, the substrate mevalonic acid accumulates in serum and urine. Higher levels are found during the episodes of fever. There is not a dramatic shortage of any specific end product; concentrations of cholesterol, ubiquinone, and dolichol in patients are normal to slightly decreased.[1]

Another syndrome was already linked to mutations in the mevalonate kinase gene before the discovery of HIDS[50]—classic mevalonic aciduria. Patients with mevalonic aciduria carry specific mutations that cause a more severe reduction of mevalonate kinase enzyme activity, reducing it to undetectable levels. These patients constantly produce large amounts of mevalonic acid and often have more than 1000 times as much mevalonic acid in their urine than do HIDS patients.[51] Patients with mevalonic aciduria also have a more severe phenotype. Classic mevalonic aciduria and HIDS are probably two extremes of a continuous spectrum of disease related to MVD.[52]

The pathogenic link between MVD and inflammation is still unclear, but there is increasing evidence for a connection between the isoprenoid pathway and inflammation. Inhibition of the isoprenoid pathway by statins, the inhibitors of HMG-CoA reductase (the enzymatic step before that of mevalonate kinase), can have anti-inflammatory effects, ranging from increased apoptosis of inflammatory cells to reduction of expression of cytokines.[53,54] In other settings, statins seem to be pro-inflammatory, most notably in a study in which stimulation with *Mycobacterium tuberculosis* or mitogens in combination with statins increased caspase-1 activation and IL-1β secretion by monocytes, through a decrease of geranylgeraniol.[15] The ex vivo IL-1β production is increased in MKD,[55,56] whereas treatment with the IL-1 blocker anakinra is beneficial.[57,58] Current evidence points to a link between the mevalonate pathway and IL-1 through alterations of isoprenylation of the small guanosine triphosphate (GTP)ase Rac1, phosphoinositide-3-kinase (PI3K), and protein kinase B (PKB).[59-62] A defect in apoptosis may also contribute to the pathogenesis of MKD.[61] Lymphocytes from patients with MKD (who had no fever at the time of blood sampling) showed a decrease in apoptosis when stimulated with anisomycin, which was not found in patients with TNF receptor–associated periodic syndrome (TRAPS) or patients with FMF.[61] Such a decrease in apoptosis would result in increased survival of

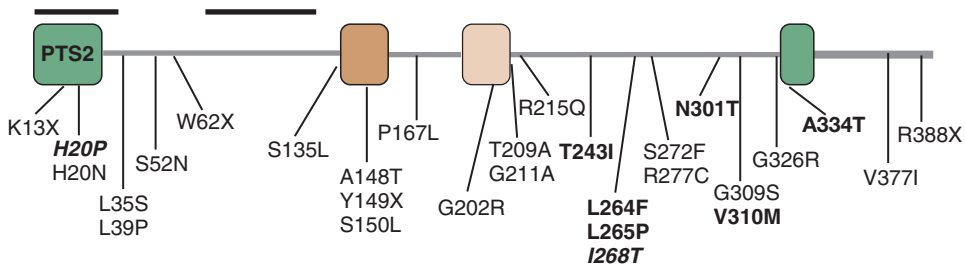

**Figure 97-5** Mevalonate kinase, with four conserved domains represented by colored boxes. Indicated are missense mutations, nonsense mutations, and two deletions *(black bars)*, which have been identified in mevalonate kinase deficiency. In *boldface* type are mutations found in mevalonic aciduria patients; in *bold and italic* are mutations found in classic hyperimmunoglobulin D syndrome and mevalonic aciduria. For complete listing of all currently known mutations, see INFEVERS website: http://fmf.igh.cnrs.fr/infevers/.

lymphocytes and may delay the resolution of the inflammatory response. An ordinarily innocuous stimulus in patients with MKD would more easily lead to a full-blown fever episode.

The cause of the characteristic high serum concentrations of IgD in this syndrome, which led to its name, is still unexplained.[62,63]

## Clinical Features

Ninety percent of patients with MKD (HIDS) experience their first fever episode in the first year of life,[42] and these episodes become most frequent in childhood and adolescence. The high fevers may lead to seizures, especially in young children. Vaccination, minor trauma, surgery, and physical or emotional stress are factors that provoke a fever episode, although often a triggering factor is not obvious.[42] The fevers often begin with cold chills and a sharp increase in body temperature. They are almost always accompanied by cervical lymphadenopathy and abdominal pain with vomiting and diarrhea. Other frequent symptoms are headache, myalgia, and arthralgia. Apart from the lymphadenopathy, physical signs frequently consist of splenomegaly and a skin rash with erythematous macules and papules (Figure 97-6) or petechiae (Figure 97-7).[42] Sometimes there are also signs of arthritis (principally large joints) and hepatomegaly. Approximately 40% of patients report painful aphthous ulcers in the mouth, vagina, or scrotum (Figure 97-8). The fever disappears spontaneously after 3 to 5 days, although it may take longer before the symptoms in joints or skin disappear completely. These inflammatory attacks occur, on average, once every 4 to 6 weeks, although this may vary from patient to patient or in an individual patient.

**Figure 97-6** Facial erythematous macules and papules in a patient with hyper-IgD syndrome during an attack.

Patients with mevalonic aciduria, the metabolic disorder that is also caused by mevalonate kinase gene mutations, experience similar but more severe inflammatory episodes versus HIDS patients. In addition, these patients suffer from psychomotor retardation, ataxia, failure to thrive, cataracts, and dysmorphic facies. Patients with classic mevalonic aciduria usually die in early childhood.[51] An intermediary clinical phenotype between classic mevalonic aciduria and HIDS has been described.[52]

## Diagnosis and Diagnostic Tests

MKD is diagnosed on the basis of a combination of characteristic clinical findings and continuously elevated IgD

**Figure 97-7** Petechiae on the leg of a patient with hyper-IgD syndrome during a febrile attack.

**Figure 97-8** Aphthous ulceration detected on the tongue of a patient with hyper-IgD syndrome. *(Courtesy Dr. K. Antila, North Carelian Central Hospital, Joensuu, Finland.)*

**TABLE 97-4** Diagnostic Indicators of Hyper-IgD Syndrome

*Extremely high serum concentrations of IgD are characteristic but not obligatory.

concentrations (>100 IU/mL) (Table 97-4). There are numerous caveats concerning IgD serum concentration, however. Values may be normal in young patients (especially patients younger than 3 years).[64] Persistently normal levels have been reported in a few patients with MKD,[43] and patients with other familial autoinflammatory syndromes may also have elevated IgD concentrations, although these are usually only slightly elevated. More than 80% of MKD patients combine a high concentration of IgD with high IgA levels.[64,65] During fever attacks, a brisk acute phase response is observed, including leukocytosis, high levels of SAA and CRP, and activation of the cytokine network.[55,66]

The diagnosis can be confirmed by sequencing the mevalonate kinase gene. The best approach is to start with screening for the two most prevalent mutations, V377I and I268T. If this screening is negative, but the clinical suspicion remains high, sequencing of the entire gene can be considered. A good alternative is the measurement of urinary mevalonic acid concentrations during an attack, which are slightly elevated. Gas chromatography–mass spectroscopy is necessary to detect this slight increase, however.[67] The measurement of mevalonate kinase enzyme activity is complicated and time consuming and should be reserved for research purposes.

## Treatment

There is no established treatment regimen for MKD. IL-1β inhibition (e.g., anakinra) reduces disease severity and is currently the most promising therapy.[68,69,70] A double-blind, placebo-controlled, crossover trial of the HMG-CoA reductase inhibitor simvastatin was beneficial, with a reduction in number of days of illness in five out of six patients[71]; however, in clinical practice, the beneficial effect is not impressive. Favorable preliminary experience with the TNF antagonist etanercept has been reported,[57,72,73] as well as with the IL-6 antagonist tocilizumab.[74,75]

Some individual patients have been reported to have benefited from treatment with corticosteroids, colchicine, intravenous Ig, or cyclosporine, but these results have not been repeated in most patients.[42] Thalidomide had no effect on disease activity in a placebo-controlled trial.[76] In severe cases of classic mevalonic aciduria, stem cell transplantation has been performed with success.[77,78]

## Outcome

The long-term outcome in HIDS is relatively benign in most patients. In some patients, the fever episodes occur less frequently and become less severe later in life, starting from late adolescence.[42] Joint destruction is rare, but abdominal adhesions are seen, resulting from repeated abdominal inflammation or unnecessary diagnostic laparotomy because of suspected acute abdomen. Amyloidosis is a rare complication in HIDS, but it has been reported.[42,79-81] Regular screening for proteinuria therefore also may be advisable in HIDS patients, especially patients with frequent and severe fever episodes.

# TUMOR NECROSIS FACTOR RECEPTOR–ASSOCIATED PERIODIC SYNDROME (TRAPS)

## Epidemiology

TRAPS has an autosomal dominant inheritance pattern. It was originally described in a large family from Irish and Scottish descent as "familial Hibernian fever."[82] It is found primarily in patients from northwestern Europe but also has been described in families from Australia, Mexico, Puerto Rico, Portugal, and the Czech Republic.[83] Any ethnic group may be affected. Other abandoned nomenclature for this syndrome includes "autosomal dominant familial periodic fever"[84] and "familial perireticular amyloidosis."[85]

## Etiology

Mutations are found in the gene for the type I TNF receptor (*TNFRSF1A*), which is located on the short arm of chromosome 12.[4] These are mainly single-nucleotide missense substitutions, located in exons 2, 3, and 4, which encode for the extra-cellular domain of *TNFRSF1A*. Many of these mutations disrupt one of the highly conserved cysteine residues involved in extra-cellular disulfide bonds of the 55 kDa type I TNF receptor protein (Figure 97-9).[86]

There are some general genotype-phenotype correlations, especially when mutations are grouped in cysteine and noncysteine mutations. Noncysteine mutations have, overall, a lower penetrance than cysteine mutations, and amyloidosis is seen far more often in association with cysteine mutations.[87] Two missense mutations in *TNFRSF1A*, P46L and R92Q, have a particularly low penetrance and are found in approximately 1% to 10% of control chromosomes. These are more likely to modify inflammation than to truly cause a separate disease entity.[87-89]

## Pathogenesis

TNF is a pleiotropic molecule that induces cytokine secretion, activation of leukocytes, fever, and cachexia. Activation of the TNF receptor by TNF causes cleavage and shedding of its extra-cellular part into the circulation, where it can then act as a TNF inhibitor. However,

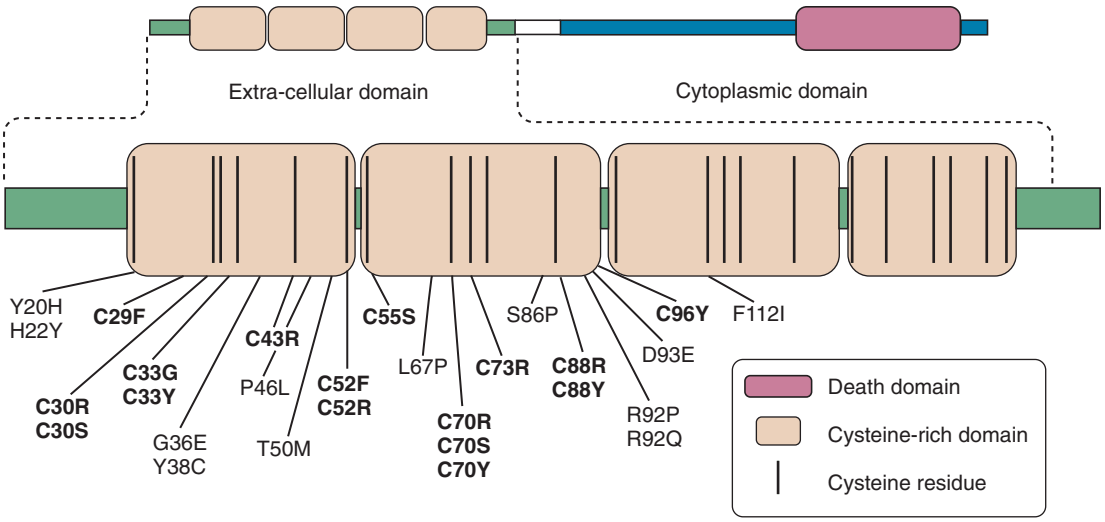

**Figure 97-9** Schematic representation of the TNF receptor type 1 protein (TNFRSF1A), depicting mutations found in TNF receptor–associated periodic syndrome up to this time (except for one intron mutation affecting a splice site). Mutations disrupting cysteine residues are in *boldface* type. For complete listing of all currently known mutations, see INFEVERS website: http://fmf.igh.cnrs.fr/infevers/.

TRAPS-associated mutations in the TNF receptor lead not to an increase but rather to a loss of TNF-signaling function, including less binding of TNF,[90,91] less cell surface expression,[91-94] and decreased TNF-induced NF-κB activation.[92,95,96] The mutated TNFRSF1A is retained intracellularly, pooled in the endoplasmic reticulum.[91,92,96,97] Mutant TNFR1 cannot associate with the wild-type version but can form aggregates by self-interaction.[91,92] This cytoplasmic receptor aggregation results in ligand-independent signaling.[96,98] Mitochondrial-derived reactive oxygen species appear to mediate this effect.[99] This new hypothesis also might offer an explanation for the observation that blocking IL-1β works better in some TRAPS patients than blocking TNF.[96,100]

An alternative hypothesis, the "shedding hypothesis," was postulated on the finding of reduced shedding, which leads to prolonged TNF signaling and uncontrolled inflammation. Not all TRAPS mutations cause decreased shedding, however, and although serum concentrations of the shedded soluble TNFRSF1A in TRAPS patients during periods without symptoms are often found to be significantly reduced compared with normal patients, this is not always the case.[1] The hypothesis of reduced shedding, although attractive by its simplicity, is not supported as the sole cause of the fever attacks in TRAPS, and additional mechanisms seem to be at work.

## Clinical Features

The clinical features can vary much more among individual TRAPS patients than is generally seen in FMF or HIDS.[83,86] The age of onset can vary, even within the same family, with a documented range of 2 weeks to 53 years old.[83,101] There is also a large variation in duration and frequency of the fever episodes in TRAPS. On average, attacks last 3 to 4 weeks and recur two to six times each year. Episodes also may be limited to a few days (see Figure 97-1). Although the index patient, through whom the diagnosis is made, often displays well-defined inflammatory attacks, affected family members may have less typical symptoms, such as episodic mild arthritis.

**Figure 97-10** Migrating erythematous rash during a TNF receptor–associated periodic syndrome attack. *(Courtesy Dr. T. Fiselier, University Medical Center St. Radboud, Nijmegen, the Netherlands.)*

During inflammatory attacks, a high, spiking fever can be accompanied by skin lesions, myalgia and arthralgia, abdominal distress, and ocular symptoms. The most common cutaneous manifestation is a centrifugal, migratory, erythematous patch, which may overlie a local area of myalgia (Figure 97-10),[102] but urticarial plaques also may be seen. Myalgia is often located primarily in the muscles of the thighs, but it may migrate during the fever episode, affecting all of the limbs and the torso, face, and neck. Arthralgia primarily affects large joints, including hips, knees, and ankles. Clinically obvious synovitis is rarer, and when it does occur it is nonerosive, asymmetric, and monoarticular.[83] Abdominal pain occurs in 92% of TRAPS patients during inflammatory attacks; other gastrointestinal symptoms often seen include vomiting and constipation. Ocular involvement is characteristic in TRAPS, and it may involve conjunctivitis, periorbital edema, or periorbital pain in one

or both eyes. Severe uveitis and iritis have been described, and any TRAPS patient with ocular pain should be examined for these complications.[83,102] Other less frequently observed symptoms during fever attacks in TRAPS are chest pain, breathlessness, pericarditis, and testicular and scrotal pain, which may be caused by inflammation of the tunica vaginalis. One case report described a patient who presented with psychosis but no fever.[103] It was initially thought that this disorder is associated with an increased incidence of indirect inguinal hernias,[104] but this was not confirmed in other case series. Lymphadenopathy is rare in TRAPS.

## Diagnosis and Diagnostic Tests

As in the other familial autoinflammatory syndromes, laboratory investigations during inflammatory attacks show a clear acute phase response, and even in between fever attacks, such an inflammatory response may be measured. The IgD level may be elevated, but the value is almost always less than 100 IU/mL.[101,104]

Hull and colleagues[83] proposed a set of clinical diagnostic criteria for TRAPS (Table 97-5). These criteria are not validated by epidemiologic measures, but they may be used as a first step in evaluation of patients. TRAPS is ultimately a genetic diagnosis, defined by a missense mutation in the gene for *TNFRSF1A*. Clinical penetrance of TRAPS mutations is not 100%, however, even for cysteine mutations, and asymptomatic carriers are common. Also, the finding of an R92Q or P46L variant in this gene would pose a difficulty. Because they have many characteristics of a polymorphism rather than a direct disease-causing mutation (see Etiology section in preceding text), it is debatable whether such a finding should lead to a diagnosis of TRAPS.

## Treatment

In mild cases of TRAPS, NSAIDs are often sufficient. NSAIDs and glucocorticoids in high doses (>20 mg/day of oral prednisone) alleviate the symptoms of fever and inflammation in most TRAPS patients, although they do not alter the frequency of attacks. They can be used beneficially at times of attack, and glucocorticoids usually can be tapered in the course of 1 or 2 weeks, as tolerated. Anti–IL-1 therapy is considered to be the most effective, from case reports and case series.[100,105-107] Use of the TNF inhibitor etanercept, a fusion product of TNFRSF1B (the receptor that is not defective) has been partially successful in reducing disease severity.[83,87,107-110,113] Infliximab, a monoclonal antibody against TNF, is less effective than etanercept in TRAPS and seems to cause increased symptoms.[108,111,112] Intravenous infusion of a synthetic TNFRSF1A fusion protein was tried in one patient by Drewe and colleagues,[108] but this seemed to provoke a severe attack.

One patient whose symptoms were resistant to administration of etanercept responded favorably to use of oral sirolimus (4 to 6 mg daily).[111] There is no response to colchicine or immunosuppressive drugs such as azathioprine, cyclosporine, thalidomide, or cyclophosphamide.[83]

From Hull KM, Drewe E, Aksentijevich I, et al: The TNF receptor-associated periodic syndrome (TRAPS): emerging concepts of an autoinflammatory disorder. *Medicine (Baltimore)* 81:349–368, 2002.

## Outcome

Reactive AA amyloidosis is the principal systemic complication of TRAPS. It occurs in approximately 15% to 25% of patients if untreated[87,114] and generally leads to renal impairment. Amyloidosis in a patient with TRAPS places other affected family members at high risk for this complication. It is principally associated with *TNFRSF1A* mutations affecting cysteine residues.[87] Because proteinuria is the initial manifestation of renal amyloidosis, urine from TRAPS patients should be screened regularly by dipstick examination, especially affected family members of a TRAPS patient with amyloidosis.

# CRYOPYRIN-ASSOCIATED PERIODIC SYNDROME

The autosomal dominant cryopyrin-associated periodic syndrome (CAPS) encompasses three clinical syndromes that all have been traced to mutations in one common gene: Muckle-Wells syndrome (MWS), familial cold autoinflammatory syndrome (FCAS), and chronic infantile neurologic cutaneous and articular syndrome (CINCA), also known as neonatal-onset multisystemic inflammatory disease (NOMID). After the recognition of the genetic defect, it became clear that there is considerable overlap among these three disorders.[115] FCAS, MWS, and CINCA/NOMID represent a spectrum of disease, with FCAS the mildest and CINCA the most severe form. Given their common genotype, they are discussed under one heading here, but clinical features and outcomes are dealt with separately.

## Epidemiology

Most articles on FCAS, first described in 1940, describe large families from Europe and North America with extensive pedigrees, but sporadic cases have been described. There seems to be a founder effect in American families of Northern European extraction.[116] MWS was first described in 1962 and has since been described in large families, although it does occur in isolated cases and small nuclear families. CINCA is rare, and, to date, some 70 cases and only a few families with the syndrome have been described.

## Etiology

The first indications that MWS and FCAS are allelic stem from early linkage studies showing that FCAS and MWS were linked to the same region on the long arm of chromosome 1 (1q44).[117,118] In 2001, the gene for FCAS and MWS was identified. In a large-scale, positional cloning effort that used three families with FCAS and one family with MWS, missense mutations in a new gene were found.[119] This gene, *CIAS1*, encodes for a protein denoted *cryopyrin* at discovery, but now generally known as NLRP3 (other names that have been used are NALP3 and PYPAF). Later studies showed that NLRP3 mutations were also associated with CINCA.[120,121] Practically all mutations are missense mutations found in exon 3 of the *NLRP3* gene, which encodes for the NOD domain of NLRP3[122] (Figure 97-11). Somatic mosaicism for *NLRP3* mutations occurs in a significant number of patients who had previously been designated as "mutation-negative" CAPS patients.[123,124]

## Pathogenesis

NLRP3 or cryopyrin was a previously unknown protein at the time of the discovery of the mutations involved in these syndromes. Since that time, it has become the focus of numerous studies, which have led to a new concept—the inflammasome.[125] NLRP3 is a member of the nucleotide-binding oligomerization domain–leucine-rich repeat (NOD-LRR) protein family.[126] It consists of a pyrin domain (PYD), a NOD (also known as NACHT domain), and a LRR domain. NLRP3 is mainly expressed in monocytes and neutrophils but is also found in human chondrocytes.[119,120,127]

NLRP3 is thought to be an intra-cellular sensor of pathogens or danger signals, regulating innate immunity. On stimulation with various ligands, which include bacterial RNA, imidazoquinolone compounds, gram-positive bacterial toxins nigericin and maitotoxin, adenosine triphosphate, and uric acid crystals, NLRP3 forms interactions with adapter proteins ASC and cardinal, which results in a multiprotein complex known as the *NLRP3 inflammasome*. The NLRP3 inflammasome activates caspase-1, which subsequently cleaves pro–IL-1β to the active IL-1β.[128,129]

There is conflicting evidence for a role of NLRP3 in the regulation of transcription factor NF-κB.[1] The ultimate effect on NF-κB is likely determined by interactions of multiple proteins. Several publications by independent groups that each developed an NLRP3-deficient mouse showed no effect, however, on NF-κB activation in these mice, whereas they did show a clear deficiency in caspase-1–mediated IL-1β activation.[1]

Monocytes from patients with mutations in the NOD of NLRP3 show increased activation of caspase-1 and subsequently increased release of IL-1β.[129,130] The key role of IL-1β in CAPS is confirmed by the success of treatment with IL-1 inhibitors all three clinical syndromes.

The exact effect of the NLRP3 mutations is still unclear. An attractive hypothesis involves a possible autoinhibitory loop of NLRP3.[130] Mutations in the NOD could interfere with this autoinhibitory mechanism of NLRP3, leading to undue and excessive activation of caspase-1 and IL-1β.[1]

## Clinical Features and Outcome

### Familial Cold Autoinflammatory Syndrome

FCAS is characterized by episodes of rash, fever, and arthralgia after generalized exposure to cold (see Figure 97-1). The disease occurs in large families as an autosomal dominant inherited disorder with an almost complete penetrance.[116] The rash usually starts on the exposed extremities and, in most episodes, extends to the remainder of the body. It consists of erythematous macules and plaques (Figures 97-12 and 97-13), urticarial lesions, and sometimes petechiae[131] and can cause a burning or itchy sensation. In one case report, FCAS was associated with Raynaud's disease.[132] In some cases, localized edematous swelling of extremities is reported. Arthralgia, present in 93% of cases, most often affects the hands, knees, and ankles but can also involve feet, wrists, and elbows.[133] Frank arthritis is not seen. Most patients (84%) also report conjunctivitis during a fever episode. Other symptoms include myalgia, profuse sweating, drowsiness, headache, extreme thirst, and nausea.

A typical feature of FCAS is the requirement of cold exposure to trigger the symptoms. The delay between cold and onset of symptoms varies from 10 minutes to 8 hours.[133] When Hoffman and colleagues[134] provoked an inflammatory attack in FCAS patients by generalized cold exposure in a cold room, patients developed rash, fever, and arthralgia

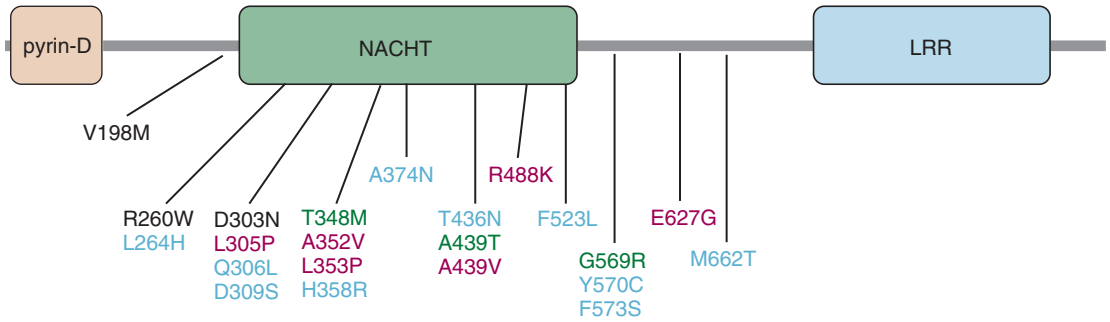

**Figure 97-11** Cryopyrin protein, containing an N-terminal pyrin domain, a nucleotide binding site (NACHT), and a leucine-rich repeat (LRR) domain. Indicated are missense mutations identified in patients with familial cold autoinflammatory syndrome *(red)*, Muckle-Wells syndrome *(green)*, or chronic infantile neurologic cutaneous and articular syndrome *(blue)*, and mutations found in common in two or all of these clinical syndromes *(black)*. For complete listing of all currently known mutations, see INFEVERS website: http://fmf.igh.cnrs.fr/infevers/.

**Figure 97-12** Fine, confluent, erythematous macules on the upper leg of a patient with familial cold autoinflammatory syndrome. *(Courtesy Dr. Johnstone, Medical College of Georgia, Augusta, Ga.)*

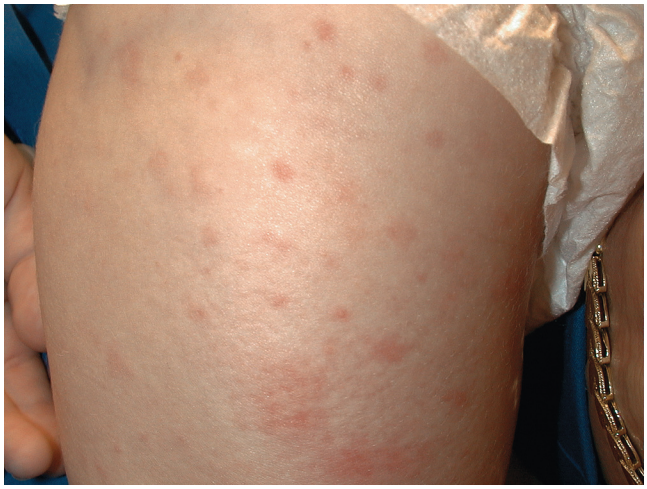

**Figure 97-13** Detail of upper leg with fine, confluent, erythematous macules in familial cold autoinflammatory syndrome. *(Courtesy Dr. Johnstone, Medical College of Georgia, Augusta, Ga.)*

within 1 to 4 hours, accompanied by increased serum and skin cytokines. The subsequent fever attack varies in length, depending on the degree of cold exposure; generally, it lasts a few hours to a maximum of 3 days. These episodes start at an early age, with 95% of patients having had their first fever episode in the first year of life—60% within the first days of life. The symptoms tend to become less severe with advancing age.[131] Type AA amyloidosis complicated by renal insufficiency has been described in at least three families with FCAS.[133]

### Muckle-Wells Syndrome

MWS is a rare autosomal dominant inflammatory disorder with incomplete penetrance. Patients have recurrent episodes of fever, abdominal pain, myalgia, urticarial rash (Figures 97-14 and 97-15), and conjunctivitis, frequently accompanied by arthralgia, arthritis with limb pain, or both.

**Figure 97-14** Urticarial skin rash in a patient with Muckle-Wells syndrome. *(Courtesy Dr. D.L. Kastner, National Institutes of Health, Bethesda, Md.)*

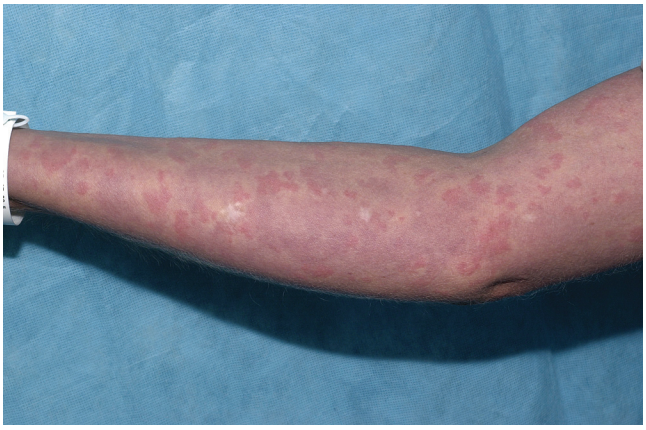

**Figure 97-15** Urticarial skin rash on the arm of a patient with Muckle-Wells syndrome. *(Courtesy Dr. D.L. Kastner, National Institutes of Health, Bethesda, Md.)*

Attacks start in adolescence and can be provoked by hunger, fatigue, and, sometimes, exposure to cold.[135] The inflammatory episodes generally last 24 to 48 hours (see Figure 97-1) and start with ill-defined malaise and transient chills and rigor, followed by aching or lancinating pains in the distal limbs and larger joints. Arthralgia is a common feature of the attacks, but synovitis of the large joints is less common.[136] The rash consists of usually aching and sometimes pruritic erythematous papules 1 to 7 cm in diameter. In a few cases, genital and buccal aphthous ulcers have been seen.[137] Ocular symptoms include uveitis and conjunctivitis. Symptoms typically start in adolescence, although they have been reported at an earlier age. Late-onset development of perceptive deafness is common in MWS. Bone involvement such as clubbing of nails and pes cavus can be seen as well. Most often, patients have a family history for the disease suggestive of autosomal dominant inheritance, but isolated cases have been reported. The most feared complication of the inflammatory attacks is type AA amyloidosis, which affects the kidneys first, leading to proteinuria and subsequent rapid progression to renal failure.

### Chronic Infantile Neurologic Cutaneous and Articular Syndrome

CINCA or NOMID is a rare congenital disorder defined by the presence of the triad of (1) neonatal-onset skin lesions, (2) chronic aseptic meningitis, and (3) recurrent fever along with joint symptoms.[138] The key clinical feature of CINCA is a skin rash accompanied by peculiar joint manifestations and central nervous system involvement. The symptoms in CINCA begin right after birth or in the first months of life with a generalized skin rash. The disease follows an unpredictable course with persistent nonpruritic and migratory rash with fever, hepatosplenomegaly, and lymphadenopathy. Central nervous system involvement is not obvious from the outset, although some patients present with seizures, spasticity, or transient episodes of hemiplegia. In most patients, there are signs of chronic persistent aseptic meningitis.[139] Cerebrospinal fluid analysis may show mild pleocytosis, and there may be increased intracranial pressure. Brain imaging shows mild ventricular dilation, prominent sulci, central atrophy, and, in long-standing cases, calcifications of fauces and dura.

In older children, headache is often a prominent feature as a sign of chronic meningitis. Mental retardation is present in many cases. Progressive sensorineural impairment leading to high-frequency hearing loss can be seen in a few cases. Ocular manifestations are prominent, with optic disc changes such as optic disc edema, pseudopapilledema, and optic atrophy, as well as anterior segment manifestations such as chronic anterior uveitis.[140] These symptoms may lead to visual impairment. Hoarseness, especially in older children, is typical. Joint and bone symptoms are a prominent feature of CINCA. Bone inflammation can give rise to major arthropathies secondary to epiphyseal and metaphyseal disorganization. Growth cartilage alterations such as enlarged epiphyses and patellar overgrowth can be an impressive feature of the disease (Figures 97-16 and 97-17). Erosive changes occur, especially in the phalanges of hands and feet. There are typical dysmorphic features such as frontal bossing and a saddle nose. These common physical features are the reason CINCA patients give the impression that totally unrelated patients are siblings. The prognosis of these patients is grave unless treated aggressively; 20% die in childhood because of infections, vasculitis, and amyloidosis.[138]

## Diagnosis and Diagnostic Tests

Diagnosis starts with a thorough patient and family history (see Table 97-1). Hoffman and colleagues[133] suggested a set of diagnostic criteria for FCAS after studying six large families with this syndrome (Table 97-6), but this requires validation. Laboratory examination during a fever episode in CAPS shows an acute phase response with polymorphonuclear leukocytosis and increased erythrocyte sedimentation rate, but this does not differentiate among the periodic fever disorders. Symptoms such as an urticarial rash after cold exposure highly favor a diagnosis of FCAS. The ice cube test (i.e., holding an ice cube to a patch of skin to provoke urticaria), which is diagnostic in acquired cold urticaria, is negative in FCAS. Typical facial features, such as frontal bossing and a long pediatric

**TABLE 97-6** Diagnostic Criteria for Familial Cold Autoinflammatory Syndrome

| | |
|---|---|
| 1. | Recurrent intermittent episodes of fever and rash that primarily follow generalized cold exposures |
| 2. | Autosomal dominant pattern of disease inheritance |
| 3. | Age of onset <6 mo |
| 4. | Duration of most attacks <24 hr |
| 5. | Presence of conjunctivitis associated with attacks |
| 6. | Absence of deafness, periorbital edema, lymphadenopathy, and serositis |

From Hoffman HM, Wanderer AA, Broide DH: Familial cold autoinflammatory syndrome: phenotype and genotype of an autosomal dominant periodic fever. *J Allergy Clin Immunol* 108:615–620, 2001.

history including chronic aseptic meningitis, point to CINCA/NOMID.

Genetic testing of the *NLRP3* gene can subsequently help to establish the genetic diagnosis. Usually, exon 3 of this gene is screened for mutations. There seems to be genetic heterogeneity because not all patients have *NLRP3* mutations. In some patients, *NLRP3* mutation somatic mosaicism occurs, which can be missed by standard DNA diagnostic tests.[123,124]

### Treatment

Since the advent of IL-1 inhibition, it is the treatment of choice for patients with CAPS.[141] Previously, high-dose oral corticosteroids were often used and could be modestly beneficial in some patients. NSAIDs, disease-modifying anti-rheumatic drugs, and cytotoxic drugs generally do not help.

The efficacy and safety of IL-1 inhibition in CAPS has been demonstrated for several available IL-1 inhibitors in diverse trials and case series. Anakinra, the synthetic IL-1 receptor antagonist, given by daily subcutaneous injection (1 to 2 mg/kg body weight; in children higher dose may be necessary) gives rapid and sustained clinical response, with decrease of symptoms, acute phase response, and leptomeningeal lesions as seen on MRI[142,143] Mirault and colleagues[144] described improvement of sensorineural deafness in a patient with MWS on treatment with anakinra.

Placebo-controlled trials of IL-1β antibody canakinumab in patients with CAPS,[145,146] demonstrated the efficacy of an injection of 150 mg canakinumab once every 2 months, although in some patients this treatment schedule needs to be adapted, either increased or decreased according to disease severity.[147] The long-acting IL-1 TRAP (rilonacept) has also been studied in a placebo-controlled setting and is effective. A subsequent 72-week open label extension study with rilonacept demonstrated sustained clinical response and safety.[148]

## BLAU SYNDROME/EARLY-ONSET SARCOIDOSIS

### Epidemiology

Blau syndrome,[149] also known as *familial granulomatous arthritis*, and early-onset sarcoidosis (BS/EOS) are now recognized as the same disorder.[150,151] "Pediatric granulomatous arthritis" has been suggested as a new name to describe this syndrome,[152] although this might, erroneously, give the impression that the disease occurs only in children. Little is known about its epidemiology, although it is thought to occur worldwide.[150]

### Etiology

The inheritance pattern of BS/EOS is autosomal dominant. In many cases, a de novo mutation is found, which explains the relatively high incidence of sporadic cases. These sporadic cases were often classified as EOS precisely because of the absence of affected relatives, but Blau syndrome and EOS are caused by mutations in the nucleotide-binding oligomerization domain 2/caspase recruitment domain 15 gene (*NOD2/CARD15*).[150,153,154] Mutations are mostly located in exon 4 of *NOD2/CARD15*. The predominant mutations are two missense mutations at position 334 (R334Q and R334W).[152]

### Pathogenesis

The NOD2/CARD15 protein is an intra-cellular sensor for pathogenic components, analogous to the Toll-like receptors. NOD2/CARD15 activation causes a wide array of downstream effects that are still not well understood, including activation of NF-κB and mitogen-activated protein kinase pathways, turning on an innate immune response of diverse cytokines (e.g., IL-1β) and defensins.[155]

Seven of the nine different mutations of *NOD2/CARD15* linked to BS/EOS are located in the NOD domain of the protein, similar to the mutations in cryopyrin (NLRP3) in the cryopyrin-associated syndromes. The two most common mutations affect a codon at a homologous position in the NOD domain to the location of the cryopyrin R260W mutation.[156] This suggests a similar pathophysiologic effect on the function of the protein.

Polymorphisms in another part of this same *NOD2/CARD15* gene on chromosome 16 are associated with increased susceptibility to Crohn's disease[157]; the risk of Crohn's disease is increased 40-fold in individuals homozygous for these polymorphisms. Whether these polymorphisms result in a gain or loss of function of this protein is debated. There are some shared features between the two diseases. Both are characterized by granulomatous inflammation, and although bowel inflammation is not seen in Blau syndrome, Crohn's disease can manifest with uveitis, arthritis, and skin rash.

### Clinical Features and Outcome

The clinical phenotype of BS/EOS consists of recurrent granulomatous inflammations. The three typical sites affected are joints, eyes, and skin.[158] The granulomatous arthritis is most often polyarticular, with a synovitis or tenosynovitis.[150] The most frequently involved joints at presentation are wrists, ankles, knees, and proximal interphalangeal joints.[158] The uveitis associated with this disorder tends to follow a chronic, persistent course. It can be an acute anterior uveitis, but it often extends to a panuveitis.[152] Cataracts, secondary glaucoma, and significant visual impairment can result. Involvement of the skin results in a papular, erythematous skin rash with associated dermal granulomas, usually generalized and intermittent, on the trunk and extremities.[159] Other symptoms outside of the classic triad are regularly seen[158] and can include campylodactyly (contracture of multiple interphalangeal joints), generalized lymphadenopathy, cranial neuropathies, recurrent fever, interstitial lung disease, and arteritis.[153,158] In some severely affected patients, granulomatous inflammation can disseminate at an advanced stage into a systemic disease, with granulomas in liver, lung, and kidney.[152] Onset is generally before age 5 years In familial cases, genetic anticipation is often observed (i.e., the course of disease tends to be more severe in later generations). The major long-term complications are joint deformity and visual impairment.[150]

### Diagnosis

The most important aspect of diagnosis is histologic evidence of granulomas at the site of inflammation. This evidence can be obtained by biopsy of any involved site, of which skin is least invasive. One study showed that skin biopsy was diagnostic in all cases with the typical skin rash, whereas synovial biopsy was not positive in all patients, perhaps because of sampling error.[152] Genetic testing is available for *NOD2/CARD15* mutations, but in some series, not all patients with a typical clinical phenotype carried a mutation in this gene.[153]

### Treatment

There are no controlled studies of management of BS/EOS patients, and little is known about the optimal treatment.[158] There tends to be a poor response to NSAIDs. A good response to the TNF inhibitor infliximab was described in case reports,[160,161] one of which also noted that etanercept did not have the same effect. IL-1 blockade by anakinra was also reported as beneficial in case descriptions,[158,162] although in two other cases anakinra was not effective.[163] Thalidomide was effective in two children in Japan.[164] The panuveitis is usually managed by topical, subconjunctival, or systemic corticosteroids.[150]

## PYOGENIC STERILE ARTHRITIS, PYODERMA GANGRENOSUM, AND ACNE SYNDROME

### Epidemiology

Pyogenic sterile arthritis, pyoderma gangrenosum, and acne (PAPA) syndrome is an autosomal dominant disorder first described by Lindor and colleagues.[165] Fewer than 20 families have been reported.

### Etiology/Pathogenesis

Wise and colleagues[166] identified mutations in the CD2-binding protein 1 *(CD2BP1)* gene as the cause of PAPA syndrome. *CD2BP1*, also known as *proline-serine-threonine phosphatase interacting protein 1* (PSTPIP1), is highly expressed in neutrophils.[122]

PSTPIP1 can form interactions with pyrin, the protein mutated in FMF.[167] The mutations in PAPA syndrome result in hyperphosphorylation of PSTPIP1,[167-169] which increases the strength of the interaction between PSTPIP1 and pyrin. The increased interaction between PSTPIP1 and pyrin increases IL-1β production. This activity correlated with a higher IL-1β production in response to lipopolysaccharide stimulation of peripheral blood leukocytes from a PAPA patient ex vivo compared with a healthy control.[167] It places PAPA syndrome in the same pathogenic pathway as FMF. Other studies report an increased production of TNF.[170,171] Dysregulated apoptosis may also be involved.[172]

### Clinical Features and Outcome

The episodic inflammation in this syndrome includes, as the name aptly indicates, symptoms of pyogenic sterile arthritis, pyoderma gangrenosum, and severe cystic acne. Lesions generally occur at the site of mild physical trauma, but sometimes no obvious trigger can be discerned.[165] The inflammation can be severe and eventually may lead to destruction of joints, muscle, and skin. Fever is not prominent in this syndrome. Onset is usually from age 1 to 16 years.[165,173] The acne generally starts early in puberty and persists in adulthood. Penetrance of disease manifestations can be incomplete, with varying presentation within a family.

### Diagnosis

No specific diagnostic test exists. Diagnosis is based on a finding of the typical constellation of symptoms and a positive family history. A specialized DNA diagnostics department would be able to perform the genetic test for PAPA syndrome. At this time, it is unknown whether this genetic test would detect all patients or whether other genes could be involved.

### Treatment

Only case reports or small retrospective series are available on treatment options in PAPA syndrome. High-dose steroids generally have a positive effect on the pyoderma gangrenosum but may be associated with increased acne.[165] Pyogenic arthritis is often responsive to intra-articular or oral corticosteroids.[173] Varying results have been reported with anti-cytokine treatment. The TNF inhibitor etanercept was reported to be beneficial,[170,174] as was the IL-1 inhibitor anakinra.[167,175,176] One patient with severe pyoderma gangrenosum did not respond to etanercept or anakinra reportedly responded to another TNF inhibitor, infliximab.[177]

## DEFICIENCY OF THE IL-1 RECEPTOR ANTAGONIST

Deficiency of the IL-1 receptor antagonist (DIRA) is a more recent discovery of a monogenetic disorder in the group of autoinflammatory diseases.[178,179] It was found in nine patients from six families, one from Newfoundland, Canada, three from the Netherlands, one from Puerto Rico, and one consanguineous family from Lebanon.

All patients were homozygous for mutations affecting the gene encoding the IL-1 receptor antagonist (IL-1ra), designated *IL1RN*.[178] These mutations resulted in an absence of secretion of IL-1ra. IL-1ra is an endogenous inhibitor of the inflammatory cytokines IL-1α and IL-1β. The patients showed signs of unopposed IL-1 signaling, leading to overproduction of other inflammatory cytokines and chemokines.

The clinical phenotype is present at birth or in the first month of life. Features include primarily cutaneous pustulosis and sterile pustulous osteomyelitis. Patients do not present with fever. Two children died of multiorgan failure secondary to severe inflammatory response syndrome at the ages of 2 months and 21 months, and a third child died at 9.5 years of complications of pulmonary hemosiderosis with progressive intestinal fibrosis.

The diagnosis is made by a combination of the clinical features and an impressive response to anakinra. Anakinra

**TABLE 97-7** Summary of Treatment Options

| Disorder | Treatment Options |
|---|---|
| FMF | Colchicine<br>In refractory cases or intolerance of colchicine: intravenous colchicine; IL-1 inhibition |
| HIDS | IL-1 inhibition, etanercept, (possibly simvastatin) |
| TRAPS | NSAIDs; IL-1 inhibition; etanercept |
| CAPS | IL-1 inhibition (anakinra, canakinumab, rilonacept) |
| BS/EOS | Corticosteroids; infliximab? |
| PAPA | High-dose steroids; IL-1 inhibition (anakinra); etanercept; infliximab |

BS/EOS, Blau syndrome/early-onset sarcoidosis; CAPS, cryopyrin-associated periodic syndrome; FMF, familial Mediterranean fever; HIDS, hyper-IgD syndrome; PAPA, pyogenic sterile arthritis, pyoderma gangrenosum, and acne; TRAPS, TNF receptor–associated periodic syndrome.

is a synthetic version of IL-1ra and thus supplements the missing protein in DIRA. Treatment with anakinra suppresses all disease symptoms, although in one patient inflammatory markers remained elevated.

## CONCLUSION

The familial autoinflammatory syndromes are characterized by recurrent episodes of fever and inflammation. This group of disorders should be considered in a patient with a history of years of such inflammatory attacks with symptom-free intervals in between (except for CINCA/NOMID, in which some symptoms and morphologic features persist). Dysregulation of the IL-1β pathway is central to many familial autoinflammatory syndromes, especially CAPS, FMF, and DIRA. Increasing availability of IL-1 inhibitors has revolutionized treatment options in many of these diseases.

The discovery of the causative genes has had an enormous impact in the field of periodic fevers. This discovery has been made possible because of the accurate phenotypic characterization of patients with periodic fever. Careful analysis and proper clustering of these patients is indispensable to allow the elucidation of the genetic background and the evaluation of possible treatment options (Table 97-7). Central periodic fever registries have afforded the opportunity to appreciate previously unrecognized symptoms, to give insight into the long-term prognosis, and to allow better evaluation of drug regimens. Despite these efforts at classification, however, many patients with periodic fever do not fall in one of the previously mentioned disease categories. Every year, new genetic disorders are recognized, and this is expected to continue.

CHAPTER 98

# Pathogenesis of Osteoarthritis

Paul E. Di Cesare • Dominik R. Haudenschild • Jonathan Samuels • Steven B. Abramson

## KEY POINTS

- Osteoarthritis is a degenerative joint disease that occurs primarily in older individuals, characterized by erosion of the articular cartilage, hypertrophy of bone at the margins (i.e., osteophytes), subchondral sclerosis, and a range of biochemical and morphologic alterations of the synovial membrane and joint capsule.
- Risk factors for developing osteoarthritis include age, joint location, obesity, genetic predisposition, joint malalignment, trauma, and gender.
- Morphologic changes in early osteoarthritis include articular cartilage surface irregularity, superficial clefts within the tissue, and altered proteoglycan distribution.
- Morphologic changes in late osteoarthritis include deepened clefts, increase in surface irregularities, and eventual articular cartilage ulceration, exposing the underlying bone. Chondrocytes form clusters or clones in an attempt at self-repair. In addition, marginal osteophytes can form.
- The matrix metalloproteinase family of proteinases degrades proteoglycans (aggrecanases) and collagen (collagenases).
- Suboptimal repair response of normal articular cartilage to injury typically results in secondary osteoarthritis.
- Chondrocytes sense and respond to mechanical and physicochemical stimuli via several regulatory pathways.
- Mediators classically associated with inflammation during the course of osteoarthritis include interleukin-1β and tumor necrosis factor.
- Nitric oxide, produced by the inducible isoform of nitric oxide synthase, is a major catabolic factor produced by chondrocytes in response to pro-inflammatory cytokines.
- Expression of inducible cyclooxygenase-2 is increased in osteoarthritis chondrocytes.
- Low-grade inflammation occurs in osteoarthritis synovial tissue and contributes to disease pathogenesis.
- Most current treatments aim to improve the signs and symptoms of osteoarthritis.

Osteoarthritis (OA) is a degenerative joint disease, occurring primarily in older people and characterized by erosion of the articular cartilage, hypertrophy of bone at the margins (i.e., osteophytes), subchondral sclerosis, and a range of biochemical and morphologic alterations of the synovial membrane and joint capsule. Pathologic changes in the late stages of OA include softening, ulceration, and focal disintegration of the articular cartilage; synovial inflammation may also occur. Typical clinical symptoms are pain and stiffness, particularly after prolonged activity.

In industrialized societies OA is the leading cause of physical disability, increases in health care usage, and impaired quality of life. The impact of arthritic conditions is expected to grow while the population both increases and ages in the coming decades.[1] Despite its prevalence, the precise etiology, pathogenesis, and progression of OA remain beyond our understanding, primarily because of multiple confounding factors. Without a clear-cut picture of how OA arises at the cellular or molecular level, many still consider it a result of "wear and tear," an inevitable consequence of aging. In fact, the accompanying biochemical, structural, and metabolic changes in joint cartilage have been well documented. It is now known, for example, that cytokines, mechanical trauma, and altered genetics are involved in its pathogenesis, and that these factors can initiate a degradative cascade that results in many of the characteristic alterations of articular cartilage in OA. More recently, it has become apparent that OA is a disease process that affects the entire joint structure, including cartilage, synovial membrane, subchondral bone, ligaments, and periarticular muscles. OA is thus better thought of as a group of overlapping disorders, of various etiologies and arising from a combination of systemic factors (e.g., genetics) and local factors (e.g., biomechanically or biochemically mediated events) that gradually converge to produce a condition with definable morphologic and clinical outcomes.[2] The definition of OA is being re-evaluated, and an expanded definition of the disease is likely to also include earlier markers of cell stress and degradation of the extra-cellular matrix initiated by micro injury and macroinjury.[3]

OA may be classified as primary or secondary according to its cause or major predisposing factor. What they all have in common is altered cartilage physiology. Primary OA is the most common type and has no identifiable etiology or predisposing cause. Secondary OA, although it has an identifiable underlying cause, is pathologically indistinguishable from primary OA. The most common causes of secondary OA are metabolic conditions (e.g., calcium crystal deposition, hemochromatosis, acromegaly), anatomic factors (e.g., leg length inequality, congenital hip dislocation), traumatic

events (e.g., major joint trauma, chronic joint injury, joint surgery), or the sequelae of inflammatory disorders (e.g., ankylosing spondylitis, septic arthritis). In the case of secondary OA arising from inflammatory joint disease, cartilage degeneration most likely results initially from degradative enzymes released from the synovium or leukocytes within the joint space and later from the mechanical attrition of a biomechanically altered extra-cellular matrix. Distinguishing between primary and secondary OA may be difficult because the clinical presentation and symptoms are often so similar.

## ETIOLOGY

Major factors affecting degree of risk for OA include patient age, joint location, obesity, genetic predisposition, joint malalignment, trauma, and gender.

### Age

Age is the risk factor most strongly correlated with OA.[4,5] OA is, in fact, the most common chronic disease in later life; more than 80% of people older than 75 years are affected, and OA increases progressively with age at all joint sites. Radiologic changes in OA increase while individuals age,[6] although these changes do not always correlate with clinical symptoms or disability.[7,8] Although clearly an age-related disease, OA is not, however, an inevitable consequence of aging. Age-related morphologic and structural changes in articular cartilage include fraying, softening, and thinning of the articular surface, decreased size and aggregation of matrix proteoglycans, and loss of matrix tensile strength and stiffness. These age-related tissue changes are most likely due to decrease in chondrocytes' ability to maintain and repair the tissue, as chondrocytes themselves undergo age-related decreases in mitotic and synthetic activity, exhibit decreased responsiveness to anabolic growth factors, and synthesize smaller and less uniform large aggregating proteoglycans and fewer functional link proteins.[4]

There also appears to be a direct correlation between chondrocyte apoptosis and cartilage degradation leading to OA. The combination of reduced cellularity, reduced synthetic activity of the remaining cells, and lower mechanical quality of the extra-cellular matrix produced by aged chondrocytes all contribute to increased OA risk. Age is an independent factor that predisposes articular chondrocytes to apoptosis for example the expression levels of specific proapoptotic genes (Fas, FasL, caspase-8, and p53) is higher in aged cartilage.[9,10] These changes in the cartilage matrix and chondrocyte biology may predispose the aged cartilage to more rapid OA progression in the event of minor injury.

### Joint Location

Although osteoarthritis occurs most commonly in weight-bearing joints,[11] age affects joints differentially.[12] A study comparing tensile fracture stress of cartilage in the femoral head and in the talus showed that it decreased progressively with age in the former but not in the latter.[13] Joint-specific age-related viability in articular cartilage may explain why OA is more common in hip and knee joints with increasing age but occurs rarely in the ankle.

### Obesity

Obesity is another important risk factor for OA.[14-16] Greater body mass index in both women and men has been shown to be associated with an increased risk of knee (but not hip) OA.[7,17,18] An increase in mechanical forces across weight-bearing joints is probably the primary factor leading to joint degeneration. Obesity not only increases the forces at weight-bearing joints, but may also change posture, gait, and physical activity level, any or all of which may further contribute to altered joint biomechanics.[19] The majority of obese patients exhibit varus knee deformities, which result in increased joint reactive forces in the medial compartment of the knee, thereby accelerating the degenerative process.[20]

Particularly in elderly obese individuals, heavy physical activity is an additional risk factor for the development of knee OA, whereas light to moderate activity does not appear to increase risk for knee OA and may in fact alleviate symptomatic knee OA by reducing body mass index.[7,17,18] Similarly, weight loss can reduce both radiographic knee OA progression and clinical symptoms. Recent evidence indicates that in obese patients with OA, significant weight loss dramatically improves functional status, with short-term results equivalent to those of patients who have undergone joint replacement.[21]

Yet recent work suggests that the association between obesity and osteoarthritis lies beyond the mechanical loading from a higher body mass index. Adipose tissue is now recognized as a metabolically active contributor to inflammatory cascades. Activated adipose tissue increases the synthesis of pro-inflammatory cytokines, including leptin, adiponectin, resistin, IL-1, IL-6, and TNF, whereas some regulatory cytokine levels such as IL-10 are decreased.[22,23] Specifically, the discovery of the obesity gene and its product leptin may have important implications for the onset and progression of OA and may increase our understanding of the link between obesity and OA. The fact that women have a greater proportion of total body fat and relatively higher levels of adipose-derived systemic leptin concentrations than men may partially account for the gender disparity in OA patients. Leptin, however, is produced not only by adipose cells but also by osteoblasts and chondrocytes, suggesting that local leptin production may play a role in OA. Significant levels of leptin were observed in the cartilage and osteophytes of patients with OA, yet few chondrocytes produced leptin in the cartilage of healthy patients. Leptin can induce anabolic activity in rat chondrocytes, and by acting as a pro-inflammatory agent may ultimately confer structural joint changes through various mechanisms.[24-26] The association between leptin levels and OA disease severity is supported by meta-analyses of adipokines in OA patients, especially in females.[27]

### Genetic Predisposition

Because of the prevalence of OA in the general population and its extensive clinical heterogeneity, the genetic contribution to its pathogenesis has been difficult to analyze.[28,29]

Two major cohorts (the Framingham Study and the Baltimore Longitudinal Study on Aging) support a genetic contribution to OA, with evidence for a major recessive gene and a multifactorial component, representing either polygenic or environmental factors.[30,31] Twin pair and family risk studies have indicated that the hereditable component of OA may be on the order of 50% to 65%.[28,32,33] Moreover, family, twin, and population studies have indicated differences among genetic influences that determine the site of OA (hip, spinal, knee, hand).[31,34,35] Further evidence supporting a genetic predisposition to OA is the demonstration of a significantly higher concordance for OA between monozygotic twins than between dizygotic twins. Genetic studies have identified multiple gene variations associated with an increased risk of OA.[36]

Inherited forms of OA may be caused by mutations in several genes that are expressed in cartilage, including those encoding types II, IV, V, and VI collagens, as well as cartilage oligomeric matrix protein (COMP).[37,38] Mice deficient in the type IX collagen gene and the matrilin 3 gene (human equivalent condition not yet reported) developed age-dependent OA-like changes in the knee and temporal mandibular joints.[39,40] Moreover, candidate genes in OA have been identified that are not structural proteins. The haplotype of a vitamin D receptor (VDR) that plays a vital role in controlling bone mineral density appears to be associated with a twofold risk of knee OA,[41-43] although the VDR locus is very close to the COL2A1 locus on chromosome 12q, and so the association may be to the result of linkage disequilibrium with the latter. In addition, the locus of the insulin-like growth factor (IGF)-1 gene has been associated with radiographic OA, as has an aggrecan polymorphic allele with hand OA.[29]

In population studies, genome-wide linkage scans have highlighted as many as seven chromosomal regions that may harbor OA susceptibility genes.[44] Chromosome 2q was positive in several scans, suggesting that this chromosome is likely to harbor one or more susceptibility genes. In a study of affected sibling pairs, a region of linkage stretching from 2q12 to 2q21 was reported for OA of the distal interphalangeal joint, and a previous study of affected sibling pairs in the United Kingdom demonstrated a broader region of linkage, stretching from 2q12 to 2q31.[44,45] Two IL-1 genes (*IL1α* and *IL1β*) and the gene encoding IL-1Ra *(IL1RN)* are located on chromosome 2q13 within a 430-kb genomic fragment. Given the importance of IL-1 in the perpetuation of cartilage damage in OA, it is possible that a proportion of the genetic susceptibility to OA may be encoded for by variation in the activity of ILs, and that for chromosome 2q this susceptibility could reside within the IL-1 gene clusters. Loughlin and colleagues, however, have provided evidence that the IL-1 gene cluster harbors susceptibility for knee OA, but not for hip OA.[44] These and other epidemiologic studies have highlighted potential differences in the degree of OA heritability among different joint groups and between the two sexes.[46,47] Additional OA candidate genes that have recently been identified, including nuclear receptor coactivator 3 *(NCOA3)* or sulfatase 2 *(SULF2)*[48] and aldehyde dehydrogenase family 1, subfamily A2 *(ALDH1A2)*.[49] Perhaps the most convincing genetic risk allele for OA involves growth differentiation factor-5 *(GDF-5)*, a member of the TGF-β superfamily.[50]

Genomic and postgenomic technology, in addition to defining susceptibility genotypes, will also lead to the discovery of genes and gene products that are overexpressed in OA tissues and that contribute to disease pathogenesis and progression.[51-53] Studies of differential gene expression in diseased tissue, in addition to elucidating pathogenic processes that lead to novel therapies, could also have two additional benefits: (1) identification of unique biomarkers that can be used for OA diagnosis or management, and (2) identification of candidate susceptibility genotypes, such as polymorphic variations of cytokines or growth factors, that may predispose to disease progression.[54] A realization from the many recent genome-wide studies on genetic OA risk factors is that although only a small portion of OA hereditability has been explained, the polygenic contributions to a single OA phenotype necessitates large sample sizes on the order of 50,000 to 100,000 individuals to be adequately powered.

Epigenetic regulation of gene expression is coming under increased scientific scrutiny in the context of OA pathogenesis. Epigenetics describe changes in gene expression that are heritable but without changes to the DNA sequence, typically resulting either from DNA methylation, histone modification, or noncoding RNA.[55] Joint and cartilage homeostasis requires a precise balance of many opposing anabolic and catabolic activities. Global changes in epigenetic mechanisms such as DNA hypomethylation can disturb this balance, as well as affect the expression of individual genes associated with OA.[56] Genome-wide differences in DNA methylation exist between osteoarthritic and healthy cartilage, and specific genes that show altered DNA methylation patterns include homeobox transcription factors, GDF-5, and others.[57] The mechanism by which changes in methylation affect gene expression is still under investigation, but it is clear that aberrant epigenetic regulation of gene expression is involved in OA pathogenesis.

## Joint Malalignment and Trauma

Joint malalignment or trauma may lead to rapid development of OA, or it may initiate a slow process that results in symptomatic OA years later. Probably as a result of progressive reduction in periarticular blood flow and the resultant decrease in rate of remodeling at the osteochondral junction, joints become increasingly congruent with age.[58,59] Altered joint geometry may interfere with nutrition of the cartilage, or it may alter load distribution, either of which may result in altered biochemical composition of the cartilage, irrespective of age. [60,61] Local factors, such as stresses related to joint use and joint deformity, also influence the development of OA.

Joint incongruence (e.g., malreduced intra-articular fractures, developmental dysplasia of the hip, recurrent dislocation of the patella) can lead to early-onset OA.[62] Repetitive, high-impact sports are strongly associated with joint injury and increase the risk for lower-limb OA.[63] Repetitive trauma at a subfracture level has been shown to accelerate remodeling in the zone of calcified cartilage, with reduplication of the tidemark and thinning of the noncalcified zone, resulting in stiffening of the subchondral bone, increased wear of the overlying cartilage, and, ultimately, development of OA.[64-66] Regular exercise is important in maintaining

articular cartilage structure and metabolic function. Recreational running and moderate low-impact activities have not been shown to increase the risk of OA in healthy individuals, and there is growing consensus that this is true even for individuals who are considered at risk for OA.

Articular cartilage is remarkably resistant to damage by shear forces; it is, however, highly vulnerable to repetitive impact loading.[67] When joints are subjected to in vitro cyclic loads that are easily borne by subchondral bone, cartilage degeneration still results.[68] This vulnerability accounts for the high frequency of OA in shoulders and elbows of pneumatic drill operators and baseball pitchers, ankles of ballet dancers, metacarpophalangeal joints of boxers, and knees of basketball players. The risk for knee osteoarthritis among participants in sports, however, may be more closely related to previous knee injury than to participation in sport alone.[69]

### Sex

OA is approximately twice as likely to develop in women than in men. Although women have a lower prevalence of OA than men before the age of 50 years, there is a marked increase in prevalence among women after 50 years, particularly in the knee.[70] Radiographic and interview data from the National Health and Nutrition Examination Survey (NHANES III), a representative cross-sectional health examination survey of the U.S. population, reported that the lifetime prevalence of radiographic knee osteoarthritis was 37.4% and that the prevalence of symptomatic knee osteoarthritis was 12.1% in adults age 60 years and older. Prevalence was greater among women than men (42.1% vs. 31.2%), and women had significantly more Kellgren-Lawrence grade 3-4 changes (12.9% vs. 6.5% in men).[71] Women have a greater number of joints involved and are more likely to exhibit clinical symptoms of morning stiffness, joint swelling, and nocturnal pain. The gender differences in OA incidence after age 50 years may be the result of post-menopausal estrogen deficiency. Articular chondrocytes possess functional estrogen receptors, suggesting that these cells can be regulated by estrogen. Nuclear estrogen receptors (ERs) have been detected in articular chondrocytes of humans,[72,73] rats,[72,74] monkeys,[72,75] and pigs,[76] and in human growth plate chondrocytes.[77]

Epidemiologic studies have linked estrogen replacement therapy (ERT) with a lower-than-expected risk of knee and hip OA in post-menopausal women. Clinical investigations of the association between OA and hormonal level in women have involved measurement of circulating estrogen levels in post-menopausal women, general radiographic evaluation of post-menopausal women, and examination of the effect of ERT on such variables as knee OA and cartilage volume.[78-81] In a 1996 study of more than 4000 women age 65 years or older who were assessed by pelvis radiographs for hip OA, Nevitt and colleagues[78] showed that women using oral estrogen faced a significantly reduced risk of hip OA. Estrogen users for 10 years or longer had a greater reduction in risk for hip OA than women who had used estrogen for less than 10 years.[78] In 1990 Hannan and colleagues[82], using weight-bearing radiographs in female participants in the Framingham Osteoarthritis Study ($n$ = 831; mean age, 73 years; age range, 63 to 93) to study the rate of knee OA, reported a modest but nonsignificant greater protective effect for radiographically detected OA in women who were on ERT.[82] A prospective cohort study using anteroposterior weight-bearing knee radiographs of women (mean age, 71 years; age range, 63 to 91) from the Framingham Study categorized patients into three groups according to estrogen use at biennial examination: never users ($n$ = 349), past users ($n$ = 162), and current users ($n$ = 40). When both incident and progressive radiographic knee OA cases were combined, current ERT users were found to have 60% less risk for knee OA than never users. Wluka and colleagues[80] reported on the longer-term use of ERT and its association with knee cartilage volume (measured by MRI) in post-menopausal women. Results showed that after adjusting for confounders, women using long-term ERT had more knee cartilage than controls. Beneficial effects of ERT on the severity of knee OA in ovariectomized monkeys has also been demonstrated.[83] In addition to hormone therapy, selective ER modulators appear to hold promise as gender-specific therapeutics in both pre-clinical and clinical studies.[84]

## PATHOLOGY

### Morphologic Changes

In early OA, the articular cartilage surface becomes roughened and irregular, and superficial clefts within the tissue become apparent. Histologically, the surface is fibrillated, and small cracks are apparent but limited to the upper layers of the surface zone. These changes show evidence of mechanical wear and are often accompanied by matrix swelling and chondrocyte proliferation, or, to a limited extent, apoptosis near the articular surface. Proteoglycan distribution is altered, as revealed by histochemical staining. While OA progresses, the articular cartilage surface becomes more irregular, and the superficial clefts within the tissue become enlarged and extend beyond the superficial zone and into the middle zone of cartilage. The previously isolated and focal portions of damaged cartilage become increasingly contiguous. Portions of the superficial zone are completely missing in focal lesions. While the condition worsens, the clefts deepen, surface irregularities increase, and the articular cartilage eventually ulcerates, exposing the underlying bone. While the disease continues to progress, the joint articulates on exposed bone, causing eburnation and thickening of the bone. The eburnated bone becomes denser and more metabolically active in response.

### Early Reparative, Proliferative, and Hypertrophic Changes in Cartilage

Attempts at local self-repair can be seen as an initial increase in the number of chondrocytes in the form of clusters or clones, with as many as 50 or more cells in a cluster[43] (Figure 98-1). In healthy cartilage, chondrocytes are quiescent and neither commit to proliferation nor to further hypertrophic differentiation. In contrast, in the early stages of OA, proliferating chondrocytes in clusters express higher levels of matrix proteins, including aggrecan and type II collagen,[85] as well as stem cell markers[86] and markers of hypertrophic differentiation,[85] The chondrocyte clusters with proliferative and hypertrophic markers are a hallmark of OA

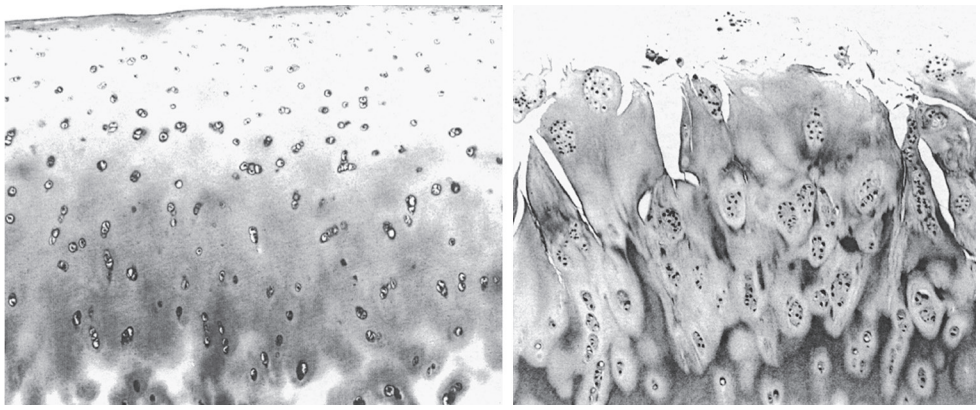

**Figure 98-1** Histologic sections of normal *(left)* and osteoarthritic *(right)* articular cartilage obtained from the femoral head. The osteoarthritic cartilage has surface irregularities, with clefts to the radial zone and cloning of chondrocytes.

and are also prominent in animal models of OA and 3D cell cultures.[87] In addition to being a repair response, chondrocyte clusters are thought to contribute to OA pathogenesis and progression through the release of matrix-degrading enzymes, growth factors, and inflammatory cytokines that affect surrounding chondrocytes and joint tissues.[87]

### Osteophyte Formation

Osteophytes consist of newly formed fibrocartilage and bone, and are most commonly formed at the peripheral margins of joints at the interface between cartilage and the periosteum. Osteophytes are thought to arise through chondrogenic differentiation of progenitor cells, most commonly from within the periosteum.[88] As such, osteophytes may be a cellular repair response to the altered growth factor environment after joint injury, and in certain cases, osteophytes can contribute to the stability of the joints.[89,90] The connection between osteophyte formation and the repair response is further strengthened by animal models of OA in which the early stages of osteophyte formation can be histologically apparent as early as 3 days after joint injury. Many growth factors that enhance in vitro chondrogenic differentiation of stem cells are also present in osteophytes, including members of the TGF-β superfamily,[91] bone morphogenetic proteins (BMPs),[92] insulin-like growth factor (IGF), and fibroblast growth factor (FGF),[88] and TGF-β, can induce osteophyte formation in animal models.[93] Although osteophytes can initially restore stability to an injured joint, while OA progresses, osteophytes can limit range of motion and become painful.

### Cartilage Hypocellularity

A reduction in cell number is observed in aging cartilage, and the reduced synthetic capability of hypocellular cartilage is a contributing factor to the initiation and progression of OA. In healthy adult femoral cartilage, the cell density varies between 24,000/mm$^3$ in the surface zone to 8000/mm$^3$ in the deep zone, with an average of 1.65% of the cartilage volume consisting of cells.[94] This number is greatly reduced in OA, through cell death via necrosis or apoptosis.[95] Necrosis can result from direct mechanical damage to cells and is not generally an active process, whereas apoptosis is an active energy-consuming process. Apoptotic chondrocyte death can be initiated by many factors that are involved in the initiation and progression of arthritis, including mechanical damage or injury, changes in cell-matrix interactions, oxidative stress resulting from nitric oxide (NO) or other reactive oxygen species, impaired mitochondrial function, and signal transduction pathways such as CD95/CD95 ligand. These pathways ultimately converge, and the execution of apoptotic cell death is mediated by the activation of caspases. Inhibition of apoptosis by interfering with caspase activation following injury is under investigation as a chondroprotective intervention to prevent secondary OA following injury. Compromised regulation of cellular senescence and autophagy can also cause cell death. The role of autophagy in inflammation and pathogenesis has been gaining attention of researchers.[96] In some circumstances cell death can be mediated by the autophagic degradation of the damaged organelles. In cartilage, autophagy can be protective, and its reduction in OA corresponds with increased apoptotic markers.[97]

## ALTERATIONS IN CARTILAGE MATRIX METABOLISM

### Biochemical Changes

These morphologic changes are accompanied by changes in the biochemical composition of the cartilage, which varies from early to later stages in the disease process. In early OA, the water content of the articular cartilage significantly increases, causing the tissue to swell and altering its biomechanical properties. This phenomenon suggests that there has been weakening of the collagen network; the type II collagen fibers have a smaller diameter than normal cartilage, and the normally tight weave in the midzone is slackened and distorted.[98-103]

In later stages of OA, type I collagen concentration within the extra-cellular matrix increases and the proteoglycan concentration falls to 50% or less than normal, with less aggregation and shorter glycosaminoglycan side chains.[99,104] Keratan sulfate concentration decreases, and the ratio of chondroitin-4-sulfate to chondroitin-6-sulfate

increases, reflecting synthesis by chondrocytes of a proteoglycan profile more typical of immature cartilage.[105] Proteoglycan concentration in the cartilage diminishes progressively until the end stages, when histologic staining detects little or none.[106]

Our understanding of the how the biochemical changes progress from the early to the later stages of OA is evolving. One of the first steps in cartilage degradation is a decrease in the density of proteoglycans. This step is thought to be at least partly reversible.[107] However, decreased proteoglycan density opens up the cartilage porosity to make it more permeable to collagenases and other proteases, and it exposes collagen fibrils. This initiates a vicious circle of positive-feedback loops that further promote cartilage degradation. For example, epitopes on collagen become accessible to the DDR2 receptor on the cell surface, which then increases matrix metalloproteinase (MMP)-13 production through activation of the Ras/Raf/MEK/ERK and p38 signal cascades.[108] The partially digested matrix components themselves have cytokine-like activity that enhances the inflammatory response and promotes matrix degradation. The destruction of the collagenous cartilage component is thought to be irreversible.

Calcium crystals (e.g., calcium pyrophosphate dihydrate [CPPD], basic calcium phosphate crystals) are commonly found in the cartilage of the elderly, and often crystal arthropathy coexists with OA.[109] The fact that calcium crystals play a role in causing or worsening OA is supported by clinical and laboratory studies, but the relationship is complex, and it is unclear whether these crystals are directly involved in OA pathogenesis.[110-112] Pyrophosphate (PP) is produced from adenosine triphosphate (ATP) by the exoenzyme nucleoside pyrophosphohydrolase.[113] High levels of PP in synovial fluid from OA patients correlate directly with the severity of joint damage.[114,115] Young or proliferating chondrocytes are a major source of PP, whereas resting chondrocytes from normal adult cartilage secrete little.[113] Thus the increased PP secretion in OA cartilage might indicate increased chondrocyte metabolic activity toward matrix repair.[116] The presence of CPPD may alter the biomechanical properties of the cartilage extra-cellular matrix and lead to cartilage breakdown. Hemochromatosis (hemosiderin), Wilson's disease (copper), ochronotic arthropathy (homogentisic acid polymers), gouty arthritis (crystals of monosodium urate), and CPPD crystal deposition disease are further examples of conditions in which the abnormal entity may alter the cartilage extra-cellular matrix, leading to either direct or indirect chondrocyte injury by increasing the stiffness of the tissue and thereby precipitating the development of OA.

## Metabolic Changes

Early OA is characterized by increased synthesis of proteoglycans, collagen, noncollagenous proteins, hyaluronate, and cell replication.[106,117] This "activation" of chondrocytes is thought to be an attempt to repair the cartilage matrix, although it is not always effective and yields a matrix of inferior quality that is more susceptible to degradation.[118] However, both anabolic and catabolic processes increase while cells attempt to repair or maintain tissue integrity,[99] and it is the imbalance between synthesis and degradation that is important in the pathogenesis of OA.[119] In later stages of OA, there is a decrease in the synthesis of matrix per cell and a decrease in cell number. Furthermore, the quality of the synthesized matrix is reduced with respect to the composition and distribution of their glycosaminoglycans, the size of the proteoglycan subunit, and their ability to aggregate with hyaluronic acid.[99,103,105,120,121] In addition to the reduced matrix production and hypocellularity, there is increased synthesis and activation of matrix degrading enzymes, and an overall decrease in the concentrations of enzyme inhibitors such as tissue inhibitors of metalloproteinases (TIMPs). Eventually OA progresses when the chondrocytic anabolic repair processes cannot keep pace with catabolic processes.[99,106] The complex interaction between matrix synthesis and degradation explains why OA typically is slowly progressive and at times remains static by morphologic criteria, but ultimately results in the overall degradation of cartilage matrix. The following sections summarize the major anabolic and catabolic factors relevant to cartilage degradation and the pathogenesis of OA.

### Anabolic Factors (TGF-β, Bone Morphogenic Proteins) and Cartilage Repair

TGF-β is essential for the formation and maintenance of cartilage (reviewed in[122]). Interference with TGF-β function in cartilage leads to OA in multiple animal models[123] and in human genetic susceptibility to OA.[124] TGF-β affects cartilage homeostasis at multiple levels: It enhances stem cell chondrogenesis to increase the pool of cells available for cartilage synthesis, and it increases matrix production in existing chondrocytes. TGF-β also increases synthesis of anti-catabolic factors such as TIMPs and plasminogen activator inhibitor (PAI)-1, proteins that inhibit the activation of latent proteinases in cartilage. TGF-β attenuates the cellular response to inflammatory cytokines, including IL-1β and TNF,[122] and TGF-β signaling through the Smad2/3 pathway can inhibit terminal differentiation and hypertrophy in chondrocytes. However, TGF-β activity can also contribute to the pathogenesis and progression of OA. For example, TGF-β signaling induces osteophyte formation in animal models. In aging cells and cells in which the ratio of the TGF-β receptors ALK1 and ALK5 is altered, TGF-β can also have opposing effects, such as activating MMP-13 and inducing terminal hypertrophic differentiation in chondrocytes.[125]

BMPs are structurally related to TGF-β but generally activate a different set of receptors and intra-cellular signaling molecules. BMPs influence all stages of embryonic chondrogenesis and can promote chondrogenic differentiation of adult mesenchymal stem cells (MSCs).[126] Recent genetic evidence suggests that impaired BMP signaling affects OA susceptibility, with the most progress reported for BMP-14 (GDF-5).[127,128] There is good evidence that a reduction of BMP-7 (OP-1) is evident in osteoarthritic cartilage,[129] with possible regulation occurring through both inhibitory microRNA[130] and promoter methylation.[131] Supplementation of BMP-7 in joints reduces experimental arthritis in animals and was proven safe in a phase I clinical trial, with no findings of ectopic bone formation in the enrolled patients during the study.[132] However, as described

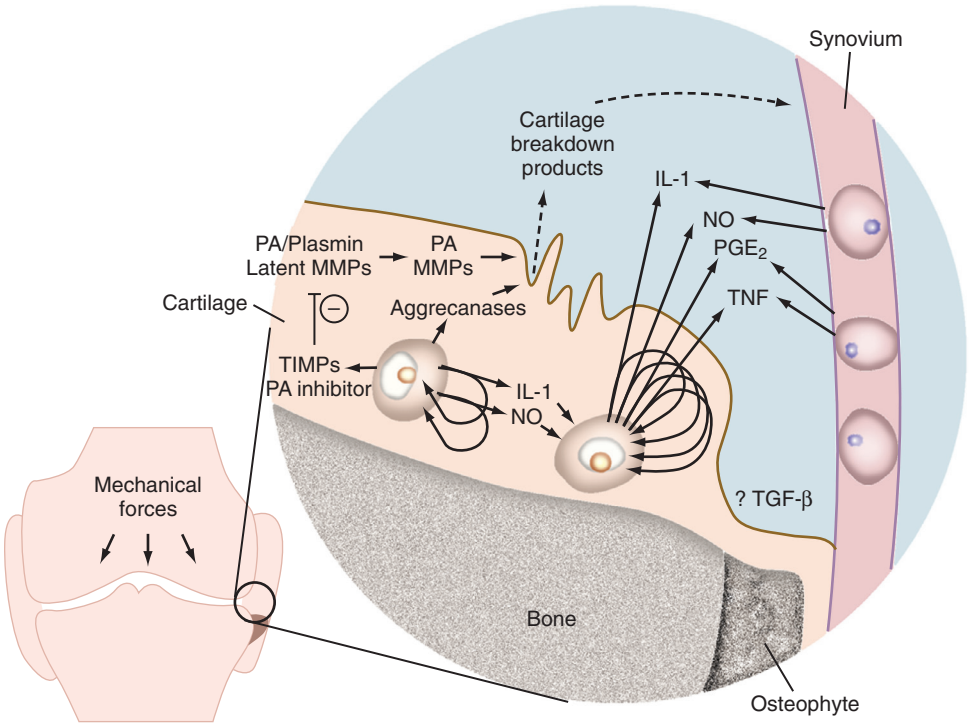

**Figure 98-2** Schematic of pathogenic mechanisms of osteoarthritis. Mechanical stress initiates altered metabolism characterized by the release of matrix metalloproteinases (MMPs), pro-inflammatory cytokines, and mediators such as nitric oxide (NO) and prostaglandin $E_2$ ($PGE_2$). Cartilage breakdown products play a role by stimulating the release of cytokines from synovial lining cells and by inducing MMP production by chondrocytes. Perpetuation of cartilage damage is amplified by the autocrine and paracrine actions of interleukin (IL)-1β and tumor necrosis factor (TNF) produced by chondrocytes. PA, Plasminogen activator; TGF-β, transforming growth factor-β; TIMPs, tissue inhibitors of metalloproteinases.

for TGF-β above, BMP signaling through certain receptors can also enhance terminal differentiation and hypertrophy in chondrocytes, processes that are hallmarks of OA progression. The effects of BMPs appear to depend on the BMP family member, with hypertrophic differentiation promoted by BMP-2 and yet suppressed by BMP-7.[133]

### Catabolic Factors and Cartilage Degradation

In addition to new matrix synthesis, cartilage remodeling also involves a degree of proteolysis. This occurs via the induction of an array of proteases, and in particular, MMPs. In OA, the cytokines IL-1 and TNF stimulate the synthesis and secretion of many proteases and MMPs (Figure 98-2).[107] IL-1 is synthesized by mononuclear cells (including synovial lining cells) in the inflamed joint and by chondrocytes as an autocrine activity.[134-136] The enzymes stimulated by IL-1 and TNF include latent collagenase, latent stromelysin, latent gelatinase, aggrecanase, and tissue plasminogen activator (TPA).[137-140] Plasminogen is either synthesized by the chondrocyte or enters the matrix by diffusion from the synovial fluid. TPA converts plasminogen to plasmin, a serine proteinase that can activate latent cartilage-degrading enzymes. A downstream mediator of IL-1– and TNF-induced cartilage degradation that is gaining increasing attention is hypoxia-inducible factor (Hif) 2α.[141,142] Hif2α is a transcription factor strongly upregulated in OA cartilage and mouse models of OA. It directly induces the expression of many cartilage-degrading enzymes, including MMP-1, -3, -9, and -12 as well as a disintegrin and metalloproteinase with thrombospondin motifs (ADAMTS)-4 and, (indirectly), ADAMTS-5. In addition, a high level of Hif2α decreases the protective role of autophagy, increases the extent of cell death, and activates the RUNX2 and IHH pathways that further contribute to cartilage matrix degradation. The different classes of proteinases that are activated by these cytokines in OA are discussed in more detail below.

## CLASSES OF PROTEINASES

In OA, the synthesis and secretion of matrix-degrading enzymes by chondrocytes markedly increases.[106,117,143-145] There are four classes of proteases, which are grouped by the catalytic mechanisms of peptide bond cleavage: metalloproteinases, cysteine proteinases, serine proteinases, and aspartyl proteinases. Of these, the first three have clearly defined roles in the degradation of cartilage during the progression of OA.

### Metalloproteinases

Metalloproteinases have an enzymatic site that requires a metal ion (often zinc) for activity. Cartilage contains two families of metalloproteinases, namely ADAMTSs and MMPs. Early cartilage degeneration in OA is most likely the result of metalloproteinase enzymatic activity. Both families of metalloproteinases are upregulated in osteoarthritic cartilage, and both are highly expressed in OA cartilage at lesional sites. Because the MMPs and ADAMTSs

play major roles in the degradation of cartilage extra-cellular matrix, several MMPs and ADAMTSs are candidate targets for disease modification.[146]

The control of metalloproteinase activity in OA is complex, with regulation occurring at three different levels: synthesis and secretion, activation of latent enzyme, and inactivation by proteinase inhibitors.[147] Most metalloproteinases are not constitutively expressed, but their transcription is induced after stimulation with cytokine and growth factor signaling. Once transcribed, the transcript stability and translation of several metalloproteinases are regulated by microRNA. For example, microRNA-27b (miR-27b) regulates MMP-13 expression.[148] Also, miR140 levels are decreased in OA, which reduces its repression of ADAMTS-5.[149] Several of these miRNA are controlled by the same cytokines and growth factors that maintain cartilage homeostasis, including IL-1 and TGF-β. Although the microRNA field is still in its infancy, it is already evident that several miRNAs are involved in the pathogenesis of OA by affecting transcript stability and protein translation. Once translated into proteins, almost all MMPs are expressed as inactive proenzymes (zymogens) that require further processing for full proteolytic activity. Most MMPs contain an N-terminal prodomain that blocks or otherwise inhibits the catalytic site. The primary MMP activators are serine- and cysteine-dependent proteases (e.g., the plasminogen/plasmin cascade or furin-like proprotein convertases, and cathepsin B, respectively), as well as membrane-type MMPs.[120,150,151] Activated MMPs can then be inactivated nonspecifically by alpha-2-macroglobulin, and with more specificity by the tissue inhibitor of metalloproteinase (TIMP) family of proteins.

MMPs have historically been further divided into three groups based on their substrate specificities; *collagenases* cleave across all three chains of the native triple-helical collagens, whereas *gelatinases* preferably cleave denatured collagen, and *stromelysins* have much broader substrate specificities.[152] However, there is considerable overlap in substrates between these classifications; for example, MMP-1 (interstitial collagenase), MMP-3 (stromelysin 1), and MMP-13 (collagenase-3) are all capable of cleaving aggrecan core protein.[153] MMPs can degrade other cartilage extra-cellular matrix molecules in addition to collagen. If combined with plasmin (that has the capability of activating many MMPs), MMPs can rapidly destroy cartilage altogether.

## Collagenases

Collagenases typically make the first cleavage in triple-helical collagen, allowing its further degradation by other proteases. Degradation of collagens is thought to be the first irreversible first step in the pathogenesis of OA because it significantly reduces the mechanical properties of cartilage. The best-studied MMPs capable of cleaving native collagens are MMP-13 and MMP-1, although MMP-8 and MMP-28 are also involved in breaking down type II collagen. Of the MMPs that degrade native collagen, MMP-13 may be the most important in OA, because it preferentially degrades type II collagen.[154] Mice deficient in MMP-13 resist developing OA, and have reduced cartilage erosion even after proteoglycan loss.[155] Expression of MMP-13 greatly increases in OA[156]; overall collagenase activity also markedly increases in human osteoarthritic cartilage cultures, suggesting that it is a major factor in OA progression and cartilage matrix degradation.[157,158] The resultant collagen fragments may then be susceptible to further cleavage by such other enzymes as MMP-2 (gelatinase A), MMP-9 (gelatinase B), MMP-3, and cathepsin B (a cysteine proteinase).

## Cathepsins

Cathepsins are a class of cysteine proteinases that can be secreted into the extra-cellular space, and can further activate MMP proenzymes. Of particular interest in OA pathogenesis is cathepsin K (known roles in bone resorption and osteoporosis), which can proteolytically cleave type II collagen and aggrecan in cartilage.[159] Cathepsin K is elevated in the synovial fluid of OA patients, cathepsin K activity is apparent in a post-traumatic model of mouse OA,[160] and treatment with cathepsin K inhibitors is protective in preclinical models of OA.[161,162]

## Aggrecanases

The aggrecanases are metalloproteases that belong to a family of extra-cellular proteases known as ADAMTS.[163] Two aggrecanases, ADAMTS-4 and ADAMTS-5, appear to be major enzymes in cartilage degradation in arthritis.[164] The roles of these enzymes appear reversed in human and mouse OA. Whereas ADAMTS-4 is predominantly associated with aggrecan degradation in human OA, in mouse models of OA, ADAMTS-5 is more important.[165-167] Recombinant ADAMTS-4 and ADAMTS-5 cleave aggrecan at five distinct sites along the core protein, and all resultant fragments have been identified in cartilage explants undergoing matrix degradation. The G1 region of aggrecan is highly resistant to proteases; however, a glutamate-alanine bond within the extended region between G1 and G2 is remarkably susceptible to proteolytic degradation.[168] Aggrecanase proteolytic activity can be modulated by altered expression, by activation by proteolytic cleavage at a furin-sensitive site, by binding to the aggrecan substrate through the C-terminal thrombospondin motif, by activation through post-translational processing of a portion of the C-terminus, and by inhibition of activity by the endogenous inhibitor tissue inhibitor of metalloproteinases 3 (TIMP-3). ADAMTS-4 and ADAMTS-5 activity is also detected in joint capsule and synovium and may be upregulated in arthritic synovium at either the message level or through post-translational processing. In addition to ADAMTS-4 and -5, several MMPs are also capable of cleaving aggrecan in vitro (MMP-1, -2, -3, -7, -8, -9, -13, and 28), as are ADAMTS-1, -8, -9, and -15.[169] It has been shown that ADAMTS-7 and -12 both bind to and degrade COMP (a prominent noncollagenous protein in cartilage) and that the latter is highly upregulated in osteoarthritic cartilage.[170,171] ADAMTS-4, -19, and -20 also have been show to degrade COMP in vitro; however, their in vivo activity in osteoarthritis has yet to be determined.[172,173]

A specific hyaluronidase has not been found in articular cartilage matrix, but one or several lysosomal enzymes that can cleave both hyaluronic acid and chondroitin-6-sulfate

have been implicated.[150] There are six or seven potential hyaluronidases in the human genome, and of these, hyaluronidase-1, -2, -3 and PH-20 are likely to be active in cartilage.[174] However, experimental evidence to date suggests that these enzymes are either exclusively lysosomal or can exist both in the lysosome and at the plasma membrane. Thus, although there is convincing evidence of extracellular degradation of hyaluronan, the precise role of the hyaluronidases in this process has not yet been clearly identified. The decrease in chondroitin sulfate chain length in osteoarthritic cartilage may be to the result of digestion by synovial fluid hyaluronidase, which may diffuse into the matrix as its permeability increases.[105] Evidence to support this theory is the finding that the hyaluronic acid concentration in OA cartilage is low, even though its rate of synthesis is considerably greater than normal.[106,117] These degradative enzymes serve to disrupt of the proteoglycan aggregate. The early result of the MMP-induced tissue degradation is thinning of the collagen fibers, loosening of the tight collagen network, and the consequent cartilage matrix swelling seen in OA.

### Enzyme Inhibitors

The balance of active and latent enzymes is controlled to some extent by at least two enzyme inhibitors: TIMP and PAI-1.[145,175,176] TIMP and PAI-1 are synthesized in increased amounts under the regulation of TGF-β.[168,177,178] If insufficient concentrations of degraded TIMP or PAI-1 are present in the matrix along with active enzymes, then increased matrix degradation occurs. Expression profiling of all known members of the MMP, ADAMTS, and TIMP gene families in normal cartilage and cartilage from patients with OA has revealed that several members are regulated in OA. Genes that showed increased expression in OA were MMP-2, -9,-13, -16, -28, ADAMTS-2, -12, -14, -16, and TIMP-3 (all at $P < 0.05$). Genes with decreased expression in OA were MMP-1, -3, -10; ADAMTS-1, -5, -9, and -15; and TIMP-1 and -4.[179] These results illustrate the complexity of the events that occur within the extra-cellular matrix regarding regulation of tissue-degrading enzymes.

## ALTERATIONS IN MATRIX SYNTHESIS

Much of what is known about changes in the extra-cellular matrix in early OA comes from animal models (e.g., the rabbit partial meniscectomy model, the canine anterior cruciate ligament–deficient model).[180,181] These animal models represent secondary OA, produced by internal derangement of the joint, and therefore may not precisely simulate the state of affairs in primary OA. Models for spontaneous osteoarthritis are reviewed and their pre-clinical utility compared in a recent review.[182] Of particular interest is an iodoacetate model, validated as the first pain model of osteoarthritis, in which intra-articular injection of iodoacetate in rats has been shown to lead to cartilage degeneration associated with pain and manifesting as time- and concentration-dependent alterations in hind limb weight bearing.[183,184] That not all animal models of osteoarthritis are equivalent becomes clear when one considers the differences in therapeutic response between young and old animals and between spontaneous and surgical models.[185]

In the dog model, the first alteration seen within days after joint destabilization is an increase in cartilage water content.[186] Initially, water content increases locally, in the tibial plateau and femoral condyle cartilage, but it soon spreads to the entire joint cartilage. Proteoglycans are more readily extractable from the matrix of experimental animals than from that of controls and reflected in the serum biomarker profile after acute injury in patients.[187] These matrix changes are also seen in spontaneously occurring dog and steer OA and in experimentally induced rabbit OA.[186,188,189] The increase in water content in osteoarthritic cartilage is to the result of loss of the collagen network's elastic restraint, enabling the hydrophilic proteoglycans to swell more than normally.[190] In early-stage OA proteoglycan concentration may increase, and the cartilage may consequently become thicker than normal and exhibit increased staining for proteoglycans.[191-193] Very shortly after the increase in cartilage water, newly synthesized proteoglycans are characterized by a higher proportion of chondroitin sulfate and a lower proportion of keratan sulfate, and proteoglycan aggregation is impaired.[181,186] These abnormal changes in extracellular matrix occur before fibrillation or any other gross morphologic changes are evident and result in a generalized decrease in stiffness that occurs in grossly normal cartilage adjacent to fibrillated areas.[194] While OA progresses, focal cartilage ulcerations develop. Proteoglycan loss is accompanied by a decrease in its ability to aggregate, persistence in abnormal glycosaminoglycan composition, and a decrease in chondroitin sulfate chain length. Once proteoglycan loss reaches a critical threshold, water content, which initially increased, falls below normal.[195]

## CHONDROCYTE SENESCENCE

The term *senescence* was originally coined to describe the replicative limit of primary cells cultured in vitro, and the concept has evolved to include premature senescence, or senescence-like changes in differentiated post-mitotic cells. Senescent cells have a unique phenotype that affects both the proteins expressed by senescent cells and their and responses to extra-cellular stimuli. Furthermore, the impact of senescence is not limited to the cells undergoing senescence; rather, the senescent cells have an impact on surrounding cells through the paracrine effects of the altered protein secretions.[196]

Premature chondrocyte senescence in OA is thought to be enhanced by oxidative injury.[197] The inflammatory cytokines IL-1β and TNF that are active in OA induce oxidative stress in chondrocytes, thereby contributing to the potential for oxidative injury that leads to senescence. Oxidative injury is also induced with excessive mechanical shear and injurious loading of explants, and this may contribute to the accumulation of senescent chondrocytes in aged cartilage.[198] TGF-β can influence both growth arrest and senescence in cultured cells, and senescent cells can overexpress TGF-β, but this effect has mostly been demonstrated in endothelial cells and not cells of mesenchymal origin. In summary, although it is clearly evident that many of the cellular mechanisms controlling senescence are also active in disease progression including OA, a causal link between senescence and OA has yet to be identified.

## BIOMECHANICS AND DISEASE MECHANISMS

### Biomechanical Changes

Two long-standing biomechanical theories of the pathogenesis of OA hold that mechanical stresses injure chondrocytes, causing them to release degradative enzymes, and that mechanical stresses initially damage the collagen network (as opposed to the cells per se).[199,200] In either case, the result is a breakdown of the matrix. Extra-cellular matrix breakdown in osteoarthritic cartilage leads to (1) loss of compressive stiffness and elasticity, resulting in greater mechanical stress on chondrocytes, and (2) an increase in hydraulic permeability, resulting in loss of interstitial fluid during compression and increased diffusion of solutes through the matrix (including the movement of degradative enzymes and their inhibitors). One important consequence is disruption of normal fluid film joint lubrication and loading dynamics due to alterations in inflammatory synovial fluid.[201-203] Joint friction, wear, lubrication, and contact mechanics are further negatively affected by the loss of cartilage proteoglycans and superficial zone protein (also called *lubricin*).[204-208]

### Muscle Weakening in Mechanical Loading

The major forces on articular cartilage, in addition to weight bearing, are caused by the contraction of the muscles that stabilize or move the joint.[70] For example, in normal walking 4 to 5 times the body weight, and in squatting as much as 10 times body weight, may be transmitted through the knee.[43] Articular cartilage is believed to be too thin to be an effective shock absorber under these high loads. What protects the joint under physiologic conditions of impact loading is joint motion, with the associated lengthening of muscles under tension and deformation of the subchondral bone.[42,70] With aging comes a weakening of these muscles, which correlates with the onset of osteoarthritis. Causative relationships have been investigated between sarcopenia and OA progression, as well as thigh muscle strength and OA. One study showed that sarcopenic obesity was more closely associated with OA than non-sarcopenic obesity.[209] However, data from the Osteoarthritis Initiative suggest that over 4 years the loss of muscle cross-sectional area is not different between painful and non-painful knees,[210] and a comparison of knees with early radiographic OA and contralateral knees with no OA did not support a correlation between loss of muscle cross-sectional area and OA.[211]

### Response of Cartilage to Mechanical Injury

The response of normal articular cartilage to injury typically results in suboptimal repair; these injuries can often result in secondary OA.[212,213] Articular cartilage produces a repair tissue with neither the original structure nor properties of normal cartilage.[214-217] Chondrocytes in areas surrounding an injured zone are unable to migrate, proliferate, repopulate, or regenerate repair tissue with similar structure, function, and biomechanical properties of normal hyaline cartilage.[195,215,218]

That articular cartilage lacks regenerative power has a long history of documentation.[219] In 1851, Redfern reported that articular cartilage wounds healed with fibrous tissue, which he believed arose from chondrocyte intercellular substance.[220] Fisher and Ito in the 1920s proposed that cartilage repair is effected by fibrous tissue resulting from proliferation of cells from bone marrow, synovial membrane, and, occasionally, surrounding articular cartilage.[221,222] It was later observed that the fibrous tissue regenerate subsequently transforms into fibrocartilage, with occasional foci of imperfect hyaline cartilage.[223-226] The common findings of these investigators was that articular cartilage lacks regenerative potential and that the regenerative fibrous tissue and fibrocartilage tissue must have originated from undifferentiated mesenchymal tissue arising from bone marrow, synovium, or the superficial layer of articular cartilage.[219]

One reason the reparative process of cartilage significantly differs from those of other tissues is that it is avascular. The healing response in vascularized tissues consists of three main phases: necrosis, inflammation, and repair.[212,217] Cartilage undergoes the initial phase of necrosis in response to injury, although typically less cell death occurs than in vascularized tissues because of chondrocytes' relative insensitivity to hypoxia.[212,217] The inflammatory phase, primarily mediated (in other tissues) by the vascular system, is largely absent in partial-thickness injuries (i.e., lesions that do not cross the tidemark), and the repair phase is severely limited given the lack of vascularity and a preceding inflammatory response. Thus no local hyperemia results, no fibrin network is produced, no subsequent clot develops to act as a scaffold for the ingrowth of repair tissue, no mediators nor cytokines are released that can stimulate cellular migration and proliferation, and no inflammatory cells, which have mitotic and reparative potential, are recruited.[195,217] In lesions that do not cross the tidemark, the burden of repair falls on the chondrocytes,[217] in a process that has been termed *intrinsic repair*.[227] Although fetal cartilage is capable of mitotic activity and replication, adult chondrocytes have little potential for replication and intrinsic repair.[225,226] Articular cartilage lesions that cross the tidemark may undergo extrinsic repair via differentiation and proliferation of MSCs from para-articular connective tissues; typically however, a fibrocartilaginous regenerate results.[227]

There are three categories of articular cartilage injury: (1) microdamage or repetitive trauma to the matrix and cells; (2) partial-thickness or superficial injuries or chondral fractures, articular surface injuries that do not penetrate the subchondral plate; and (3) osteochondral (full thickness or deep penetrating) injuries, which extend through the tidemark and into the underlying subchondral bone.[212,215,217] The host response to each type of injury differs in both timing and quality of repair.

Microdamage to the chondrocytes and/or extra-cellular matrix without gross disruption of the articular surface can be caused by a single severe impact or repetitive blunt trauma.[212,215,217] Repetitive loading of rabbit cartilage produces a surface loss of proteoglycans and an increase in chondrocyte metabolic activity.[228] Proteoglycans become more easily extractable from the articular cartilage, with a greater percentage of non-aggregated forms.[195] The cellular,

metabolic, and biochemical changes after repetitive blunt trauma resemble those in the early stages of OA: increased hydration, cellular degeneration and/or death, disruption of the collagen ultrastructure resulting in marked variation in the size and arrangements of fibers, fissuring and ulceration of the articular surface, thickening of the subchondral bone, and softening of the cartilage with loss of its compressive and tensile stiffness.[195,215,229-232] Trauma induces the release of degradative enzymes and pro-inflammatory factors (e.g., NO, TNF, IL-1) that frequently cause degradation of the surrounding matrix.[228,233,234] Eventually the material properties of the cartilage are altered—cartilage matrix thins and subchondral bone stiffens—which in turn often accelerates the degenerative process.[195] The point at which accumulated microdamage becomes irreversible is unknown, although it has been demonstrated that lost proteoglycans and matrix components may be restored if damage to chondrocytes and the collagen network is limited and the repetitive trauma is halted.[215]

Necrosis of neighboring chondrocytes follows chondral fractures and superficial lacerations, injuries that do not cross the tidemark.[212,217,235] Within 48 to 72 hours, surviving chondrocytes bordering the defect exhibit increased synthesis rates of extra-cellular matrix molecules and type II collagen, sometimes accompanied by cell proliferation and formation of clusters or clones in the periphery of the injured zone.[195,217,235,236] The increased metabolism and mitotic activity is transient, however, and is followed by a fall in metabolic rate back to normal levels, typically resulting in a suboptimal repair.[195,217] Chondrocytes proliferating on the border of the injured zone do not migrate into the defect, which remains unfilled by the newly synthesized matrix.[195,215,218] In some cases, superficial lacerations in otherwise normal joints may not progress to full-thickness loss of cartilage or OA.[195]

Lesions that cross the articular cartilage tidemark and disrupt the underlying subchondral plate elicit the three-phase repair response normally encountered in vascularized tissues. A hematoma forms in the defect that becomes organized into a fibrin clot, activating an inflammatory response. Transformation of the fibrin clot into vascular fibroblastic repair tissue[217,236] is accompanied by release of cytokines important in stimulating a repair response (e.g., TGF-β, platelet-derived growth factor, IGF, BMPs).[214] These cytokines help set in motion the recruitment, proliferation, and differentiation of undifferentiated cells into a fibrin network that serves as a scaffold for fibrocartilaginous repair tissue.[214,237,238] The origin of these MSCs has been determined to be primarily from the underlying bone marrow,[236,238,239] although there is also evidence of cartilage progenitor cells resident in other joint tissues such as the fat pad and synovium, and even within the cartilage itself.[240-242] These cells progressively differentiate into chondroblasts, chondrocytes, and osteoblasts and synthesize cartilage and bone matrices. At 6 to 8 weeks post-injury, the repair tissue contains a high proportion of chondrocyte-like cells surrounded by a matrix consisting of proteoglycans and type II collagen, with a lesser amount of type I collagen.[239,243,244] Cells in the deeper layers of the defect differentiate into osteoblasts and subsequently undergo endochondral ossification to heal the subchondral bone defect.[195]

This regenerative tissue eventually undergoes a transformation to a more fibrocartilaginous repair accompanied by a shift in the synthesis of collagen from type II to type I.[218,235,237,238,244] Typically, within 1 year from injury, the repair tissue resembles a mixture of fibrocartilage and hyaline cartilage, with a substantial component (20% to 40%) of type I collagen.[243] The size of the osteochondral defect is an important factor in the quality of repair; as a general rule, the smaller the defect the better the repair.[245] Depending on the joint, there exists a critical size defect that will not repair. Fibrocartilaginous repair is susceptible to early degenerative changes because it lacks the biomechanical properties to withstand normal physiologic joint loads.[238,243]

## MECHANOTRANSDUCTION AND GENE EXPRESSION

Chondrocytes can sense and respond to mechanical stimuli via several regulatory pathways (e.g., upstream signaling, transcription, translation, post-translational modification, vesicular transport).[246] Chondrocytes can remodel extracellular matrix in response to alterations in functional demand because physical forces influence the synthesis, assembly, and degradation of the extra-cellular cartilage matrix. High magnitude or duration loads can also cause chondrocyte death and collagen damage, and chondrocytes in the superficial zone appear to be more vulnerable to load-induced injury than those in the middle and deep zones.[247,248] Normal stimuli help chondrocytes maintain the extra-cellular matrix; abnormal stimuli can disrupt this balance.

Mechanotransduction influences the cell-mediated feedback between physical stimuli, the molecular structure of newly synthesized matrix molecules, and the resulting biomechanical tissue properties.[249] Cell-matrix interactions via integrins are believed to be the one of the important mediators in mechanotransduction in chondrocytes. In a study on the expression of COMP related to long-term cyclic compression, it was found that uniaxial unconfined dynamic compression, significantly upregulated COMP expression, which could be blocked by incubation with anti–α1-integrin antibodies.[250] Studies of bovine articular cartilage explants showed that cyclic loading increased protein synthesis by as much as 50% above free-swelling controls and had an inhibitory influence on proteoglycan synthesis, whereas static compression reduced biosynthetic activity.[251] Fibronectin and COMP were the most affected noncollagenous extracellular proteins; static compression caused a significant increase in fibronectin synthesis versus free-swelling control levels, and cyclic compression caused a significant increase in synthesis of COMP and fibronectin.

Human articular chondrocytes use the α5β1 integrin as a mechanoreceptor: mechanical stimulation signals via stretch-activated ion channels, the actin cytoskeleton and focal adhesion complex molecules.[252] The result is an anabolic response, manifested by increased aggrecan and decreased MMP-3 expression. Mechanical stimulation also activates Rho and Rho kinase pathways, which are linked to changes in the actin cytoskeleton.[253,254] Stimulation of the Rho/ROCK pathway in this context is an anabolic stimulus that leads to nuclear translocation and activation of SOX9, which is a "master regulator" of cartilage gene

expression.[255] Indian hedgehog (Ihh) protein is a key signaling molecule that controls chondrocyte proliferation and differentiation and may also be an essential mediator of mechanotransduction in cartilage: Cyclic mechanical stress was shown to induce Ihh expression by chondrocytes.[256]

Dysregulation of these anabolic pathways is thought to contribute to the progression of OA. For example, whereas the α5β1 integrin is also mechanosensitive in OA chondrocytes, the downstream signaling pathways differ, leading instead to increased cartilage breakdown.[257] Integrins and integrin-associated signaling pathways are at least partly regulated by mechanical stimulation by activation of plasma membrane apamin-sensitive $Ca^{2+}$-activated $K^+$ channels; the result is membrane hyperpolarization after cyclic mechanical stimulation.[258] Chondrocytes from normal articular cartilage exhibit membrane hyperpolarization response to cyclic pressure-induced strain, whereas chondrocytes from osteoarthritic cartilage respond by membrane depolarization and exhibit no changes in aggrecan or MMP-3 mRNA following mechanical stimulation.[259,260] The different signaling pathways responding to mechanical stimulation in healthy versus OA chondrocytes may affect the disease outcome.

In addition to cell and matrix deformation, fluid flow is also sensed by chondrocytes. A study using a tissue shear-loading model to uncouple fluid flow from cell and matrix deformation demonstrated that deformation of cells and pericellular matrix alone stimulated protein and proteoglycan synthesis.[261]

## ABNORMALITIES OF BONE

### Osteophyte Formation

Osteophytes—bony proliferations at the joint margins and in the floor of cartilage lesions—are in part responsible for the pain and restriction of joint movement in OA. Human osteoarthritic joint osteophytes synthesize cartilage with significant amounts of type I collagen and nonaggregating proteoglycans.[262] In experimentally induced OA, osteophytes may develop even though the articular cartilage appears grossly normal.[263] Osteophytes may result from penetration of blood vessels into the basal layers of degenerating cartilage, or as a result of abnormal healing of stress fractures in the subchondral trabeculae near the joint margins.[264,265] In the OA dog model, periarticular osteophyte formation begins in the marginal zone, where synovium merges with periosteum and articular cartilage, as early as 3 days after induction of knee instability.[266] Bony proliferation may result from venous congestion; in human hip OA, phlebography has demonstrated the formation of medullary varices, presumably because of changes in the medullary sinusoids, which may be compressed by subchondral cysts and thickened subchondral trabeculae.[267,268] Subchondral cysts in OA may be created by entry of synovial fluid under pressure through defects in the cartilage or may develop in necrotic areas of subchondral bone.[269] The increased venous pressure caused by the cysts and remodeled trabeculae may account for some of the pain in OA. Immobilization and glucocorticoids (but not bisphosphonates) have been shown to decrease the size and prevalence of osteophytes in experimental models of OA.[270-273]

### Subchondral Bone Sclerosis

Cancellous subchondral bone functions as a major shock absorber due to its material properties.[65] Two-thirds of subchondral bone stiffness derives from bony trabeculae, approximately one-third from intra-osseous fluid.[274] In the normal unloaded joint, the opposing surfaces are not congruous; under loading, both the cartilage and the bone deform so that a larger proportion of the opposing surfaces comes into contact, increasing joint congruity and resulting in a force distribution over the largest possible area.[275] Excessive loads may cause microfractures of subchondral trabeculae that heal via callus formation and remodeling, resulting in stiffer-than-normal bone that is less effective as a shock absorber and predisposing articular cartilage to degeneration.

Whether subchondral sclerosis precedes the onset of OA or is a change secondary to cartilage degeneration is not known. Indirect evidence supports the theory that biomechanical changes in subchondral bone may be important in OA.[274,276,277] Foss, for example, reports cases of femoral osteoporosis (which is associated with softening and greater compliance of the subchondral bone) that may have protected the hip from OA.[278] Conversely, in vitro studies have shown that stiffening of the cancellous bone with methacrylate, reducing its deformability, leads to cartilage degeneration with repetitive impact loading.[279] OA patients receiving bisphosphonates to slow bone resorption, showed an early benefit on reduced OA pain and a trend toward less joint space narrowing,[280] yet bisphosphonate treatment of patients with established hip OA did not prevent OA structural progression.[281] In pre-clinical models, preemptive treatment to slow bone resorption was effective in reducing arthritis severity.[282,283] Increased remodeling and hardening of subchondral bone is evident early in osteoarthritis, and can sometimes be detected before loss of cartilage thickness is evident radiologically.[284] An advancing tidemark of calcified cartilage is observed in OA, which changes the mechanical interface between subchondral bone and cartilage and is associated with increased subchondral vascularity. The increased calcification results in a thinning cartilage layer, which increases the mechanical stress in the adjacent cartilage. In combination with subchondral bone sclerosis, the altered mechanical environment and rapid bone remodeling may be contributing factors in cartilage degradation and OA pathogenesis.

### Bone Marrow Lesions

Bone marrow lesions (detectable by MRI) are associated with OA, and studies suggest that they contribute to the pain felt by OA patients.[285] The presence of bone marrow lesions is predictive of OA progression, the development of cartilage defects and degradation, and the need for joint replacement.[286] The relationship between bone marrow lesions and cartilage degeneration in OA is still under investigation. For example, a longitudinal study also found that the presence of cartilage defects predicts progression of bone marrow lesions, and the study authors suggest that it "remains unclear whether bone marrow lesions precede, accompany, or follow cartilage damage and volume loss in OA."[286] To address this question, a study using the

Osteoarthritis Initiative database examined patients with no radiographic OA during a period of time, and found that the presence of bone marrow lesions, and especially multiple types of bone marrow lesions, correlated well with both symptomatic and radiographic OA.[287]

Fibrosis and necrosis of the underlying bone marrow are common histologic features of the lesions visible by MRI, as are high bone turnover, altered trabecular structure, and edema. Unlike cartilage loss, bone marrow lesions are not a permanent structural change in OA. Several reports demonstrate that these lesions can resolve or at least regress, although it is more commonly observed that bone marrow lesion scores increase with time.[274] It has been postulated that edema-like lesions are less severe and reversible, whereas more advanced fibrotic and necrotic lesions are not.[288] There is a possibility that synovial fluid entering the subchondral bone marrow through intra-articular defects leads to an altered growth factor and cytokine environment that affects bone turnover. These findings suggest that there may be an altered biomechanical property of the subchondral tissues, which in turn would affect the biomechanical stresses experienced by the adjacent cartilage.

## ROLE OF INFLAMMATORY MEDIATORS IN DISEASE PROGRESSION

Whereas levels of inflammatory cytokines such as IL-1, IL-6 and TNF are elevated in the serum of patients with knee osteoarthritis,[289] these and other classic inflammatory mediators are activated within the joint tissues themselves during the course of OA. These cytokines autocatalytically stimulate their own production and induce chondrocytes to produce proteases, chemokines, NO, and eicosanoids such as prostaglandins and leukotrienes. The action of these inflammatory mediators within cartilage is predominantly to drive catabolic pathways, inhibit matrix synthesis, and promote cellular apoptosis. Thus, although osteoarthritis is not conventionally considered an inflammatory disease, "inflammatory" mediators from the affected tissues perpetuate disease progression and therefore represent potential targets for disease modification.

### Inflammatory Molecules Produced by Articular Cartilage

#### Cytokines and Chemokines

A characteristic feature of established osteoarthritis is the increased production of pro-inflammatory cytokines, such as IL-1β and TNF, by articular chondrocytes. Both IL-1β and TNF exert comparable catabolic effects on chondrocyte metabolism, decreasing proteoglycan collagen synthesis and increasing aggrecan release via the induction of degradative proteases.[143,290-295] IL-1β and TNF also induce chondrocytes and synovial cells to produce other inflammatory mediators, such as IL-8, IL-6, NO, and prostaglandin $E_2$. The actions of both cytokines are in part mediated by the activation of the transcription factor nuclear factor-κB (NF-κB), which further increases their own expression and that of other catabolic proteins such as inducible NO synthase and COX-2, thus creating an autocatalytic cascade that promotes self-destruction of articular cartilage[296,297] (Figure 98-3). Mounting evidence suggests that NF-κB mediates chondrocytes' pro-inflammatory stress responses in OA and also controls the differentiation of these cells, making NF-κB–activating factors attractive OA therapeutic targets for many reasons.[298] IL-1β and TNF are both synthesized intra-cellularly as precursors, converted through proteolytic cleavage to their mature forms by caspases—membrane-bound IL-1β–converting enzyme (ICE) and TNF-converting enzyme (TACE)—and released extra-cellularly in their active forms.[299] The expression of both ICE and TACE has been shown to be upregulated in OA cartilage.[263-265] Inhibitors of both ICE and TACE are of interest as future therapeutic small-molecule antagonists of downstream IL-1β and TNF expression, respectively. A pre-clinical model of mouse joint injury indicates that local, but not systemic, inhibition of IL-1 prevented osteoarthritis, and interestingly, that inhibition of TNF had no effect.[300] This is in contrast to a study in rabbits in which intra-articular injections of TNF inhibitor protected against experimental OA,[301] and small-scale clinical trials show some potential benefit of TNF inhibitor therapy suggesting that the activity of TNF is involved in OA pathogenesis.[302]

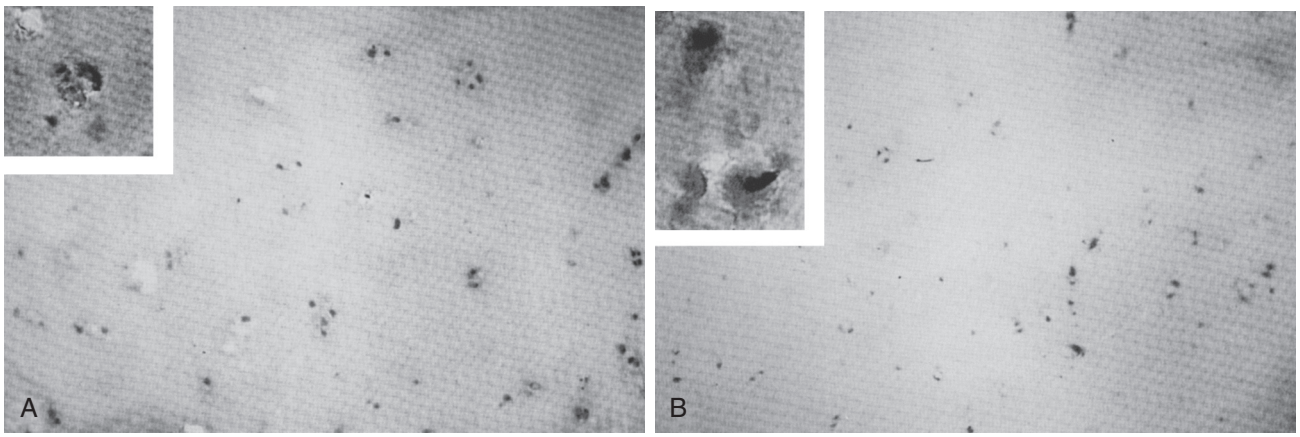

**Figure 98-3** Immunostaining of osteoarthritic cartilage specimen for inducible nitric oxide synthase **(A)** and interleukin-1β **(B)**. Note intense staining of chondrocytes in the superficial zones for both inflammatory proteins. *(From Melchiorri C, Meliconi R, Frizziero L, et al: Enhanced and coordinated in vivo expression of inflammatory cytokines and nitric oxide synthase by chondrocytes from patients with osteoarthritis,* Arthritis Rheum *41:2165–2174, 1998.)*

The actions of IL-1 are dependent upon the engagement of two specific cell surface receptors (IL-1R), designated type I and type II. The type I receptor, which spans the plasma membrane, is responsible for signal transduction, whereas the type II receptor is a "decoy" receptor, expressed at the cell membrane but unable to signal. A relative deficit of the ratio of IL-1Ra (the competitive inhibitor to the IL-1/IL-1R complex) to IL-1 has been described in OA synovial tissue, which may permit increased IL-1 activity.[303,304] Addition of IL-1Ra, or soluble type I and II IL-1 receptors, to OA explant cultures blocks prostaglandin $E_2$ ($PGE_2$) synthesis, collagenase production, and NO production;[290,305] addition of these antagonists in culture also results in an increase in aggrecan content, likely by inhibiting degradation of newly synthesized molecules.[306] One study showed that chondrocytes with abnormal morphology, from macroscopically intact cartilage representative of early OA, demonstrated increased levels of cell-associated IL-1 and loss of type VI collagen.[307]

Encouraging results with IL-1Ra have also been reported in vivo, where gene therapy or the intra-articular administration of IL-1Ra has been shown to retard the progression of OA in experimental animal models.[308,309] Other lines of evidence also point to IL-1B as an essential link in the pathogenesis of cartilage damage, including proteoglycan loss by intra-articular injection of IL-1.[308] Clinical trials using IL-1B antagonists in OA are few and have been inconclusive. One multicenter trial with double-blinded doses of intra-articular IL-1Ra to 14 OA patients resulted in decreased pain without significant adverse events or acute injection reactions.[310] A second clinical trial found short-term improvement of OA pain outcomes with intra-articular injections of IL-1Ra, but no long-term studies of structure-modifying effects of such therapies have been reported.[311]

Osteoarthritic cartilage is also the site of increased production of both CXC and CC chemokines. These include IL-8, monocyte chemoattractant protein (MCP)-1, and normal T cell–expressed and secreted (RANTES: regulated on activation, normal T cell expressed and secreted; also known as CCL5) chemokine, as well as the receptors CCR-2 and CCR-5.[293,312,313] The expression of chemokines is low or undetectable in normal chondrocytes unless stimulated with cytokines such as IL-1 or IL-17.[314] Chemokines are detected by immunohistochemistry in the superficial and midzones of the tissue, as has been demonstrated for such other inflammatory mediators as inducible NO synthase (iNOS), IL-1β, and TNF.[312] RANTES induces expression of its own receptor, CCR-5, suggesting an autocrine/paracrine pathway of the chemokine within the cartilage. MCP-1 and RANTES promote chondrocyte catabolic activities, including induction of NO synthase, increased MMP-3 expression, inhibition of proteoglycan synthesis, and enhancement of proteoglycan release.[312,315] Consistent with these effects, treatment of normal articular cartilage with RANTES increases the release of glycosaminoglycans and profoundly reduces the intensity of safranin O staining.[312]

### Proteinases

A presumed key action of cytokines and chemokines produced in osteoarthritis is to promote cartilage proteolysis via the induction of a wide array of proteases, in particular MMPs. The two main families of MMPs are (1) the collagenases that break down type II collagen (especially MMP-1, -8, -13, and -28) and proteoglycans (MMP-3, which also cleaves pro-MMPs into their active forms), and (2) the aggrecanases, also known as the ADAMTS family, which mediate aggregen degradation in cartilage.[179,190] Both families of MMPs are expressed in OA cartilage at lesional sites, where it presumed that they play a major role in degradation of the extra-cellular matrix. A recent comprehensive analysis of specific metalloproteinases that are overexpressed by OA cartilage and synovium has revealed several MMPs and ADAMTSs that may be candidates as targets for disease modification.[146] Among the most interesting is MMP-13, which is overexpressed in murine and human OA cartilage and is the most efficient protease capable of cleaving type II collagen.[237,316] Similarly, the aggrecanase ADAMTS-5 has surfaced as the aggrecanase required for aggrecan loss in experimental OA[166] and inflammatory joint disease.[165] It has been demonstrated that mice lacking ADAMTS-5 are protected from developing OA.[166]

The expression and degradation of noncollagenous proteins and nonaggregating proteoglycans are also altered in OA cartilage and may have a direct or indirect effect on modulating the catabolic state of the chondrocyte.[317] These groups of molecules are likely to have important structural and/or biologic functions.[318,319] From their interactions with other extra-cellular matrix constituents, they can influence the supramolecular assembly of the cartilage matrix and, as a result, affect the physical properties of the tissue; by interacting directly with chondrocytes and/or neighboring cells, they can provide biologic signals on matrix properties and thereby influence cellular function.[320]

### Nitric Oxide

Nitric oxide, produced by iNOS, is a major catabolic factor produced by chondrocytes in response to pro-inflammatory cytokines such as IL-1β and TNF.[293] Considerable evidence indicates that the overproduction of NO by chondrocytes plays a role in the perpetuation of cartilage destruction in OA[321-323] (Figure 98-4). Increased concentrations of nitrites have been demonstrated in the synovial fluid of patients with OA, and iNOS has been demonstrated in OA synoviocytes and chondrocytes by in situ hybridization and immunohistochemistry.[324,325] Whereas normal cartilage does not express iNOS or produce NO without stimulation by cytokines such as IL-1, OA cartilage explants spontaneously produce large amounts of NO;[321] iNOS is also upregulated from chondrocytes by cartilage compression.[326,327]

NO exerts multiple effects on chondrocytes that promote articular cartilage degradation.[328] These include (1) inhibition of collagen and proteoglycan synthesis,[328] (2) activation of metalloproteinases,[329] (3) increased susceptibility to injury by other oxidants (e.g., $H_2O_2$),[330] and (4) apoptosis.[305] Several studies have implicated NO as an important mediator in chondrocyte apoptosis, a feature common in progressive OA.[330,331] Immunohistochemistry of joint tissue obtained from patients with OA reveals co-localization of iNOS protein and apoptosis in articular cartilage cells.[332] There is evidence that apoptosis results from the formation of peroxynitrite, a toxic free radical produced by the

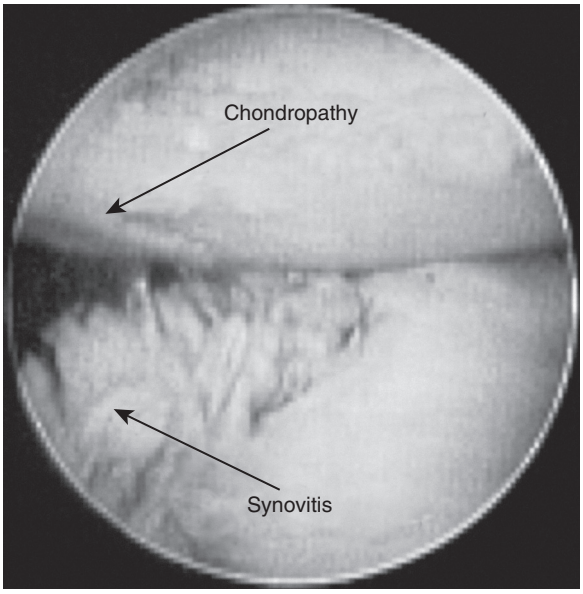

**Figure 98-4** Arthroscopic view of osteoarthritic lesion of the femoral condyle (designated chondropathy). Note that proliferative synovitis is localized to the area of the osteoarthritic lesion. *(Courtesy Maxime Dougados.)*

reaction of NO and superoxide anion. Peroxynitrite reacts with tyrosine residues on proteins, which can be detected by antibodies to nitrotyrosine. Immunostaining of OA cartilage reveals that chondrocytes that are highly positive for IL-1β also stain for nitrotyrosine, consistent with overproduction of peroxynitrite and oxidative damage.[325] The importance of NO has been corroborated in animal models of OA. In the Pond-Nuki canine model, the inhibition of NO reduced the progression of cartilage lesions.[333]

### Transforming Growth Factor-β

In most respects, TGF-β acts as a counter-regulatory molecule that opposes the effects of inflammatory mediators in cartilage. TGF-β1 has been shown to downregulate proteolytic MMP-1 and MMP-13 as well as IL-1 and TNF receptors on OA chondrocytes.[334] TGF-β2 selectively suppresses the cleavage of type II collagen by collagenases in OA cartilage in culture and limits MMP and pro-inflammatory cytokine expression.[294] Studies using the murine knee osteoarthritis model indicate that TGF-β3 protects articular cartilage, because histologic staining for this molecule revealed a lack of TGF-β3 in damaged cartilage in comparison with normals. Although premature osteophyte chondrocyte clusters express high levels of TGF-β3, other data suggest that BMP-2 is more responsible for the development of late osteophyte development.[335] Of note, TGF-β1 may also exert selected catabolic effects via the stimulation of ADAMTS-4 expression.[334]

### Hyaluronic Acid

Hyaluronic acid (HA) has been investigated as a marker of cartilage degradation that can be detected in synovial fluid and serum (see subsequent section Biomarkers of Osteoarthritis),[336] but it also appears to play a role in limiting the progression of arthritis. Karna and colleagues. found that HA in vitro counteracts the ability of IL-1β to inhibit collagen biosynthesis. At the transcriptional and post-transcriptional levels, chondrocyte cultures with IL-1β upregulated collagen synthesis markers, whereas HA negated this effect.[337] The same group found that HA similarly protects against IL-1-induced inhibition of collagen synthesis in human skin fibroblasts at the level of the IGF-I receptor.[338]

### Prostaglandins

The expression of inducible cyclooxygenase-2 (COX-2) is increased in OA chondrocytes, which spontaneously produce $PGE_2$ ex vivo.[313] The effects of prostaglandins on chondrocyte metabolism are complex, and include enhanced type II collagen synthesis, activation of metalloproteinases, and promotion of apoptosis.[339] In cartilage explants, IL-1β induces COX-2 expression and $PGE_2$ production coordinates with proteoglycan degradation. COX-2 inhibition prevents IL-1β–induced proteoglycan degradation, which can be reversed by the addition of $PGE_2$ to cultures.[340] In contrast, in vitro evidence has accumulated that selected NSAIDs) may interfere with proteoglycan synthesis.[341] Of note, another study concluded that as much as 30% of $PGE_2$ expression in OA synovial tissue stems from the COX-1 pathway.[342] Whether any differences exist between the effects of COX-1– and COX-2–derived prostaglandins on cartilage metabolism is unknown.

### F-Spondin

A novel mediator in OA cartilage, F-spondin is a neuronal extra-cellular matrix glycoprotein that appears to regulate cartilage degradation through the TGF-β and $PGE_2$ pathways. One recent article reported a sevenfold increase in expression in human OA cartilage and a significant upregulation in knee cartilage surgical specimens from rats with OA. Addition of F-spondin in vitro to OA cartilage tissue led to increased levels of activated TGF-β and production of $PGE_2$, as well as accelerated collagen degradation and reduced proteoglycan synthesis that are both dependent on these two molecules.[343]

## Inflammatory Mediators in Bone

The inflammatory mediators produced by bone in OA are less well understood than those produced by cartilage and synovium. Biomechanical and biochemical factors seem to influence the remodeling, but the underlying pathogenesis has yet to be identified. NO plays a role in bone cell function, which could have implications for OA insofar as it contributes to alterations in subchondral bone. The endothelial isoform endothelial cell NO synthase (ecNOS) is constitutively expressed in bone, where it seems to play a key role in regulating osteoblast activity and bone formation. ecNOS also mediates the effects of mechanical loading on the skeleton, where it acts along with prostaglandins to promote bone formation and suppress bone resorption.[344] In contrast, pro-inflammatory cytokines, such as IL-1 and TNF, induce iNOS in bone cells, and NO derived from this pathway potentiates bone loss.[293] Osteophyte formation and

subchondral bone remodeling likely result from local production of anabolic growth factors such as IGF-I and mostly TGF-β, which is highly expressed in osteophytes of the femoral head in OA patients.[345,346] Areas of increased radionuclide uptake ("hot spots") on bone scintigraphy have also been reported to identify OA joints more likely to progress by radiographic criteria—and/or to require surgical intervention—over a 5-year period.[260]

## Abnormalities of Synovium

Synovial lining inflammation and synovial effusions have emerged as another key feature of OA pathophysiology. OA has traditionally been classified as a non-inflammatory arthritis, largely because the synovial fluid leukocyte count in OA is typically fewer than 2000 cells/mm$^3$. Such parameters can be misleading, as low-grade inflammatory processes nevertheless occur in osteoarthritic synovial tissues and contribute to disease pathogenesis, and some degree of synovitis has been observed even in early OA. This localized synovitis may be subclinical because arthroscopic studies suggest that localized proliferative and inflammatory changes of the synovium occur in as many as 50% of OA patients, and the activated synovium may produce proteases and cytokines that accelerate damage to the adjacent cartilage.[345,346] More recently, musculoskeletal ultrasound has provided a reliable noninvasive method to detect both synovial hypertrophy and even small effusions in OA patients, using both gray-scale and power Doppler methods.[347]

Many of the clinical symptoms and signs seen in OA joints (e.g., joint swelling and effusion, stiffness, occasional redness) reflect synovial inflammation. Synovial histologic changes include synovial hypertrophy and hyperplasia with an increased number of lining cells, often accompanied by infiltration of the sublining tissue with scattered foci of lymphocytes. In contrast to rheumatoid arthritis (RA), synovial inflammation in OA is mostly confined to areas adjacent to pathologically damaged cartilage and bone. This activated synovium can release proteinases and cytokines that may accelerate destruction of nearby cartilage.[345] Whereas synovial macrophages and macrophage-produced mediators result in key inflammatory cascades and cartilage destruction in both OA and RA, it appears there may be differences between the diseases in levels of the cytokines and how they mediate destruction of the cartilage.[348]

As described earlier, the metalloproteinases that degrade cartilage are produced not only by the cartilage itself but also by the synovium. Although cartilage destruction might be directed by the chondrocytes, some degree of synovitis exists in patients even with mild OA. A comprehensive analysis by Davidson and colleagues reported several pro-inflammatory genes significantly elevated in the synovium that had not previously been reported.[146] Cartilage breakdown products, derived from the articular surface as a result of mechanical or enzymatic destruction of the cartilage, can provoke the release of collagenase and other hydrolytic enzymes from synovial cells and macrophages (Figure 98-5).[349,350] Cartilage breakdown products are also believed to result in mononuclear cell infiltration and vascular hyperplasia in the synovial membrane in OA.[351-353]

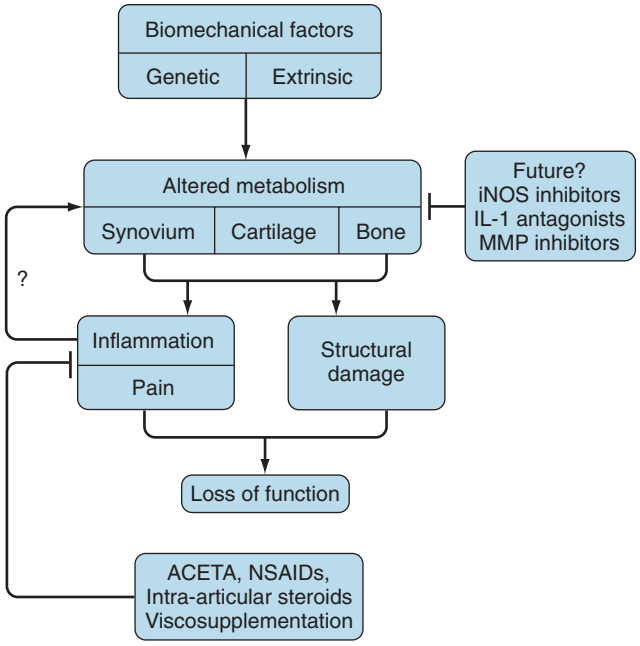

**Figure 98-5** Multiple factors that predispose to, initiate, and perpetuate osteoarthritis. In the future, structure-modifying treatments will be targeted to the biochemical processes that promote disease progression. ACETA, Acetaminophen; iNOS, inducible nitric oxide synthase; MMP, matrix metalloproteinase.

A consequence of the low-grade inflammatory processes is the induction of synovial IL-1β and TNF, which are likely contributors to the degradative cascade.[293] There are also reports of increased numbers of immune cells in synovial tissue, including activated B cells and T lymphocytes, as well as evidence that OA patients express cellular immunity to the cartilage proteoglycan link protein and C1 domain.[342,343] Histologic changes in OA synovium usually demonstrate mild or moderate synovitis characterized by an increase in the number of inflammatory mononuclear cells in the sublining tissue, including activated B cells and T lymphocytes.[354-359] A recent study of 10 patients with early OA (arthroscopic specimens) and 15 patients undergoing total knee arthroplasty revealed that synovial tissues from early OA had higher levels of IL-1β and TNF and increased mononuclear cell infiltration compared with late OA.[360]

Along the lines of acute episodes of OA, the inflammation may result from crystal-induced synovitis (either calcium apatite or calcium pyrophosphate dihydrate). "Milwaukee shoulder syndrome" represents a rapidly destructive form of OA with evidence of inflammation in the synovial membrane but minimal synovial fluid leukocytosis. It is typically associated with rotator cuff degeneration, severe shoulder OA, and hydroxyapatite crystal deposition in the synovial membrane.[361] The synovial fluid typically contains few cells and high levels of active collagenase. It is theorized that crystals released from the degenerating tendons trigger the release of collagenase from synovial mononuclear cells that leads to cartilage breakdown; cartilage breakdown products then further activate release of enzymes from the synovium. This inflammation is typically associated with increases in synovial IL-1 and TNF that further proteinate the degradative cascade.[362]

## BIOMARKERS

The aims of biomarker research in OA are early detection before irreversible damage occurs, predicting OA progression, and monitoring response to therapeutic intervention.[363] The National Institutes of Health–funded OA Biomarkers Network has established the "BIPED" biomarker classification, with five separate categories of surrogate markers: Burden of disease, Investigative, Prognostic, Efficacy of intervention, and Diagnostic.[345] Examples of burden of disease and for prognosis for hip and knee OA include serum COMP, serum hyaluronic acid, and urinary cross-linked C-telopeptide type II collagen (CTX-II).[364] A recent survey revealed that this classification scheme was not adopted as often as anticipated, and therefore the authors undertook a systematic review of the primary OA biomarker literature to standardize the findings according to the BIPED classification.[365]

The major structural components in cartilage are type II collagen and aggrecan, which are relatively unique to cartilage. Additional constituents of articular cartilage include the proteins COMP, cartilage intermediate layer protein (CILP), cartilage link protein, matrilin, minor collagens (types I, V, VI, IX and XI), as well as hyaluronic acid. In healthy cartilage these molecules have a relatively slow turnover rate, whereas OA is characterized by enhanced synthesis and enzymatic degradation of most of these molecules. Therefore much focus in OA biomarkers has been on detecting markers of cartilage matrix synthesis and degradation.[366] The biomarkers have been made more specific through the detection of "neoepitopes" or degraded cartilage matrix fragments generated by specific proteases enhanced in OA. The turnover of subchondral bone is also enhanced in OA, although biomarkers of bone turnover have proven less specific in identifying OA, perhaps because of the continuous bone remodeling in the skeleton as a whole. In addition to markers of matrix degradation and turnover, recent advances in the proteomics and microRNA fields have enabled detection of new OA biomarkers by using unbiased screening of serum constituents in arthritic patients.[130] The slow progression of primary OA is causing researchers to refocus the search for OA biomarkers on more rapidly progressing secondary OA after acute injury.[187]

One study of 62 patients with knee OA compared MRI findings at baseline and at 1 year, as well as levels of serum HA, osteocalcin, cartilage glycoprotein 39, COMP, and urine C-telopeptide of type II collagen, and suggested that a single measurement of serum HA or short-term increases in urine CTX-II would identify patients at greatest risk for progression of OA.[367] A comprehensive study by the Biomarkers Consortium of the Foundation for the National Institutes of Health examined OA biomarkers with commercially available kits. This study concluded that three catabolic biomarkers (CTX-II, CTX-I, and NTX-I) and one anabolic biomarker (PIIANP) were associated with OA progression, and that HA was itself not significantly associated with OA progression, but used in combination with the others it contributed to the predictive power.

Although OA is not considered an inflammatory disease in the traditional sense, it definitely involves inflammatory processes that hold promise as biomarkers for OA. For example, elevated levels of the inflammatory marker C-reactive protein (CRP) appear to be predictive of radiographic progression of long-term knee OA.[293] In a study of 1025 women, higher levels of serum CRP were associated with a statistically significant increase in both prevalent and incident knee OA and greater knee OA severity; women with bilateral knee OA had higher CRP levels than those with unilateral knee OA. Compared with women in whom knee OA did not develop, those in whom it did had a higher baseline CRP than at their index test 2.5 years earlier.[368] In another study of women (age 44 to 67 years), CRP levels were statistically greater in 105 women with knee OA than in 740 women without OA. These results must be interpreted with caution, as a recent study concluded that after adjustment of CRP levels to the patients' body mass index, serum CRP levels were no longer correlated to OA.[369] In summary, these and other studies report that inflammation markers such as CRP are modestly but significantly increased in early knee OA and can be predictive of OA that will progress over time.

Several studies have identified COMP levels as helpful assessors of the potential for, presence of, and progression of OA.[370,371] This noncollagenous extra-cellular matrix protein, synthesized by both cartilage and synovium with TGF-β1 stimulation,[363] is abundant in articular cartilage.[372-375] Both the degradation and tissue distribution of COMP exhibit marked differences in normal and OA human knee articular cartilage. Synovial fluid COMP levels are higher in individuals with knee pain or injury,[376] anterior cruciate ligament or meniscal injury[376,377] and OA[376,378] than in demographically matched healthy individuals. Similarly, serum levels of COMP are often higher in patients with more rapidly progressive joint damage[313,315,379] with some studies showing this specifically in hip OA[317,379] and knee OA.[314] Although COMP is one of the most useful serum markers for OA, the lack of specificity to OA, and relatively high natural variations in serum COMP levels currently necessitate use of additional markers. The development of specific reagents to detect degradative products of COMP may increase its utility as an OA biomarker.[371] As with other biomarkers based on anabolic and catabolic processes in cartilage, serum COMP levels indicate a specific stage of OA.

## CONCLUSION

Osteoarthritis, although classically conceived of as a degenerative consequence of aging, is a disease with an increasingly well-characterized molecular pathophysiology. Biomechanical factors, particularly in the context of genetic predisposition, obesity, and malalignment, result in chemical alterations within the joint that promote cartilage degradation. Early, anabolic changes, characterized by proliferation of chondrocytes and increased matrix production, are followed by a predominantly catabolic state, characterized by decreased matrix synthesis, increased proteolytic degradation of matrix, and chondrocyte apoptosis. Many of the features of the chondrocyte in the catabolic state are related to the production of inflammatory mediators by synovium and chondrocytes that act locally to perpetuate cartilage degradation. Although current treatments improve the signs and symptoms of disease, further characterization

of the altered metabolism in synovium, cartilage, and bone that promote disease progression should lead to future treatments that prevent structural damage in osteoarthritis.

CHAPTER 99

# Clinical Features of Osteoarthritis

Amanda E. Nelson • Joanne M. Jordan

**KEY POINTS**

- Osteoarthritis (OA) is the most common form of arthritis, typically affecting the hands, hips, knees, spine, and feet.
- OA can be defined radiographically, clinically, or symptomatically.
- As more sensitive measures of damage from OA become available, such as improved imaging and molecular biomarkers, definitions may change.
- Pain and functional limitations contribute substantially to disability in OA.
- Mortality is increased among individuals with OA compared with the general population.

Osteoarthritis (OA), the most common form of arthritis, is found worldwide and is strongly associated with aging. In 2005 it affected 27 million adults in the United States.[1] OA of the knee and hip has a significant functional impact because of effects on ambulation and mobility, is the cause of the majority of joint replacement procedures,[2] and is associated with considerable medical costs. In the United States in 2012, there were 671,374 hospital discharges for knee arthroplasty and 452,615 for hip arthroplasty, with estimated aggregate charges of more than US$36 billion and US$26 billion, respectively.[3] In comparison, 10 years earlier there were 386,265 discharges for knee replacement and 332,164 for hip replacement, with aggregate charges in the US$10 billion range (Figure 99-1).[3] Given the aging of society and the obesity epidemic, we can expect the burden of OA to continue to increase substantially during the next 20 years.[3]

OA affects all of the structures in and around a joint and should be considered a failure of the total joint, with the disease process affecting cartilage, subchondral bone, synovium, ligaments/tendons, meniscus, muscle, and nerve tissues. The clinically recognizable late- or end-stage joint with OA likely represents a final common pathway of many different factors, including genetics, environment, and biomechanical contributors.

## EPIDEMIOLOGY OF OSTEOARTHRITIS

OA can be defined pathologically, radiographically, or clinically. The American College of Rheumatology (ACR) criteria for the classification of OA of the hand, hip, and knee are shown in Table 99-1.[4-6] For the hand, only clinical criteria are used, with a sensitivity of 92% and a specificity of 98%. For the hip, the sensitivity and specificity of the ACR criteria are estimated to be 91% and 89%, respectively, whereas for the knee they are 91% and 86%, respectively. Because of their high specificity, these criteria are most useful for differentiating OA from inflammatory arthropathy, but they are less useful for differentiating individuals with early OA from healthy control subjects. Compared with radiographic definitions, the ACR criteria tend to underestimate the prevalence of OA.[7,8]

Radiographic demonstration of OA usually requires the presence of a definite osteophyte or joint space narrowing on plain radiographs, although MRI-based definitions are being developed.[9] Clinical OA is usually defined by abnormalities on physical examination consistent with OA, such as nodal changes in the hands, limited and painful internal rotation of the hip, or crepitus with knee movement. Symptomatic OA is usually defined as pain, aching, or stiffness in a joint with radiographic OA. Definitions can vary according to the joint site, the frequency or intensity of symptoms, and the time span over which symptoms are assessed.

### Prevalence of Radiographic Osteoarthritis

Because of the multiple definitions of OA and different sources of study participants, prevalence estimates vary. Lawrence and colleagues[1] have reviewed a few population-based studies that have estimated the prevalence of radiographic OA at the knee. Despite variations based on radiographic technique and participant age, these studies estimate that radiographic knee OA is present in 14% to 37% of U.S. adults and is more frequent in women.[10-12] For radiographic hip OA, available estimates vary more widely, from less than 1% to 27%, depending on the population being studied.[13] It is common for hand OA to be identified radiographically, especially in older individuals, but it may not be symptomatic or functionally limiting. One large study found radiographic evidence of hand OA in at least one joint in 67% of women and 55% of men aged 55 years and older, with 28% having radiographic OA in at least two of three hand joint sites (distal interphalangeal [DIP] or proximal interphalangeal [PIP] or carpometacarpal [CMC]).[14] A review of radiographic findings in foot OA reported a prevalence of 12% to 35% for first metatarsophalangeal OA,[15] whereas another review reported a prevalence from 0.1% to 61% for radiographic midfoot and

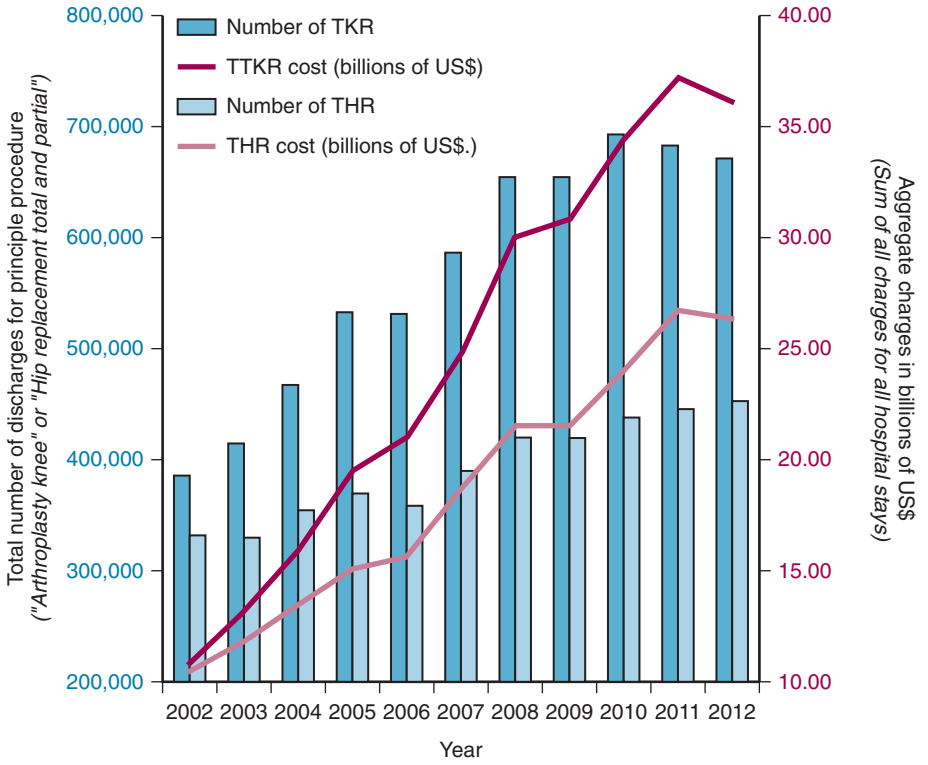

**Figure 99-1** Trends in discharge data for total knee replacement (TKR) and total/partial hip replacement (THR) in the United States from 2002-2012. The *blue bars* demonstrate the number of discharges documented in the Healthcare Cost Utilization Project National Inpatient Sample from 2002-2012 for knee *(dark blue)* and hip *(light blue)* replacement, whereas the *red lines* show the aggregate charges (sum of all charges for all hospital stays for each procedure, or the "national bill") for knee *(dark red)* and hip *(light red)* replacement. *(Generated from data on* hcupnet.ahrq.gov *on August 13, 2014.)*

forefoot OA from 30 observational and case-control studies.[16] Ankle OA, which is generally thought to be rare and usually is a result of trauma, was found to be relatively common in a cohort of patients with knee OA, with 15% having radiographic evidence of ankle OA despite a low frequency of reported injury or surgery (approximately 4%).[17] The prevalence of spinal facet joint OA is also quite high; it is reported as affecting 60% of men and 67% of women by computed tomography (CT) in the Framingham Heart Study[18] and 58% overall by radiography in the Johnston County OA Project.[19] Disk space narrowing and osteophytosis of the lumbar spine are also frequently seen on radiographs.[19]

## Prevalence of Symptomatic Osteoarthritis

A summary of prevalence estimates for symptomatic OA (i.e., symptoms in the presence of radiographic evidence of OA) of the hands, knees, and hips is presented in Table 99-2.[1] On the basis of these findings, Lawrence and colleagues[1] estimated that more than 9 million U.S. adults are affected by symptomatic knee OA and that more than 13 million have symptomatic hand OA. Nguyen and colleagues.[20] used data from the National Health and Nutrition Examination Survey (NHANES) and the Framingham study to explore trends in the frequency of symptomatic knee OA and found a dramatic increase in self-reported knee pain over approximately 20 years but no significant change in radiographic knee OA, resulting in an overall higher prevalence of symptomatic knee OA over time.

## Racial Differences in OA Prevalence

Racial differences in the prevalence of OA have been reported at several different body sites.[21] Radiographic and symptomatic knee OA were more common among African Americans compared with white people.[10,12] In the Johnston County OA Project, radiographic knee OA was present in 32% of African Americans versus 27% of whites, whereas symptomatic knee OA was present in 19% of African American and 16% of white participants.[12] Compared with white women, Chinese women had a higher prevalence of radiographic knee OA, bilateral radiographic knee OA, and symptomatic knee OA, whereas Chinese and white men had similar frequencies of these outcomes.[22] African Americans had similar[23] to slightly higher[24] frequencies of radiographic and symptomatic hip OA compared with white people, despite an apparently lower prevalence of hip OA among African populations.[25,26] Chinese people had overall lower frequencies of hip OA compared with white populations.[27] Symptomatic hand OA was present at similar frequencies in white, African American, and Mexican-American participants in NHANES III, although asymptomatic hand OA was more common in white people.[21] African Americans were much less likely to have radiographic or symptomatic hand OA phenotypes in a substudy of the Johnston County OA Project.[28,29] Compared with whites, Chinese people were also less likely to have radiographic or symptomatic hand OA.[30] Although comparisons of radiographic foot OA by race are not available in the literature, among nonobese participants in the Johnston

**TABLE 99-1** American College of Rheumatology Radiologic and Clinical Criteria for Osteoarthritis

**Hand**[5]
1. Hand pain, aching, or stiffness on most days of prior month
2. Hard tissue enlargement of ≥2 of 10 selected joints*
3. Fewer than 3 swollen MCP joints
4. Hard tissue enlargement of ≥2 DIP joints
5. Deformity of ≥2 of 10 selected joints*

Diagnosis requires items 1-3 and either 4 or 5

**Knee: Clinical**[6]
1. Knee pain for most days of prior month
2. Crepitus with active joint motion
3. Morning stiffness lasting ≤30 min
4. Bony enlargement of the knee on examination
5. Age ≥38 yr

Diagnosis requires 1 + 2 + 4, or 1 + 2 + 3 + 5, or 1 + 4 + 5

**Knee: Clinical and Radiographic**[6]
1. Knee pain for most days of prior month
2. Osteophytes at joint margins
3. Synovial fluid typical of osteoarthritis
4. Age ≥40 yr
5. Morning stiffness lasting ≤30 min
6. Crepitus with active joint motion

Diagnosis requires 1 + 2, or 1 + 3 + 5 + 6, or 1 + 4 + 5 + 6

**Hip: Clinical and Radiographic**[4]
1. Hip pain for most days of the prior month
2. ESR ≤20 mm/hr
3. Radiographic femoral and/or acetabular osteophytes
4. Radiographic hip joint space narrowing

Diagnosis requires 1 + 2 + 3, or 1 + 2 + 4, or 1 + 3 + 4

*Ten selected joints: DIP 2-3, PIP 2-3, and CMC 1 bilaterally.

Modified from Altman R, Asch E, Bloch D, et al: Development of criteria for the classification and reporting of osteoarthritis. Classification of osteoarthritis of the knee. Diagnostic and Therapeutic Criteria Committee of the American Rheumatism Association. *Arthritis Rheum* 29:1039–1049, 1986.

County OA Project, African Americans were more likely to have hallux valgus and hammer toes[31] and as likely as white individuals to have foot symptoms.[32] African Americans were less likely to have disk space narrowing, spinal osteophytes, or facet joint OA compared with white people.[19]

## Primary and Secondary Osteoarthritis

Historically, osteoarthritis was considered to be "primary" in the absence of an injury history or other joint disease and "secondary" if a predisposing disorder was present (Table 99-3). However, as more and more local risk factors for OA have been identified (such as femoroacetabular impingement at the hip and malalignment at the knee) and a broader range of associated factors have been discovered (genetic, biomechanical, and environmental), the division between primary and secondary OA is less clear. Many individuals who experience secondary OA are likely predisposed to the condition with or without the identified inciting event. Others who have a disorder that is linked to secondary OA may not experience clinical OA. It may be most useful to think of OA as a common pathway through which a person's genetics, history of injury or other joint damage, mechanical factors, and psychosocial milieu act on the joint, in some cases leading to an "end-stage" or "failed" joint.

## CLINICAL FEATURES

### General Symptoms and Signs

OA most commonly affects the knees, hands, feet, hips, and spine. These joints may be symptomatic, or signs of OA may be identified only on radiographs. People with OA generally describe pain in the joint(s) that is worse with activity, with limited morning stiffness (<30 minutes) and pain and stiffness with rest. This stiffness after inactivity, or "gelling" phenomenon, is often a main feature, although morning stiffness is generally less severe and of shorter duration than that seen in individuals with systemic inflammatory arthropathies. Affected joints in OA often demonstrate bony enlargement and crepitus on examination, with concomitant reductions in range of motion. Soft tissue swelling or effusion may be present, although these symptoms tend to be much less dramatic than in inflammatory arthritis. Reports of pain may be more or less than expected on the basis of structural damage.[33,34] The effects of depression, disturbed sleep, and other psychosocial factors on the pain experience in individuals with OA are increasingly being recognized.[35-37] Awareness is also increasing of the contribution of central sensitization (i.e., enhanced neural signaling leading to hypersensitivity) to chronic pain in OA, which can result in pain remote to the affected joint site and loss of pain inhibitory mechanisms. Ongoing study is needed to determine optimal methods of identification and treatment of this issue.[38]

### Joint-Specific Symptoms and Signs: Knee

Knee OA is characterized by the insidious onset of knee pain with gelling and limited range of motion. People with knee OA often describe pain and limitation with walking, transferring (as from seated to standing), and, especially, ascending or descending stairs. These reports of pain and limitation are often associated with a sensation of instability or "giving out" at the knee. A "locking" sensation at the knee can be a consequence of stiffness, loose bodies in the joint space, or meniscal lesions and may be reproducible using the McMurray test. Knees with OA often have demonstrable crepitus (although this symptom is likely more indicative of patellofemoral than tibiofemoral disease[39]) and bony enlargement. Pain may be elicited by palpation of the medial or lateral joint line, or both. Effusions, when present, are often cool and generally without erythema. They can be associated with popliteal bursa enlargement (a Baker cyst) when large. Associated pain over the anserine bursa, or even the greater trochanter, often occurs in individuals with knee OA and may be related to altered biomechanics.[40] Appreciation of such soft tissue symptoms is important because they may be amenable to corticosteroid injections with subsequent pain relief.

Malalignment, usually varus, is often seen in individuals with severe disease but can be present even in individuals with fairly mild/early-stage disease. Clinically evident varus thrust may be a risk factor for progression.[41] Other signs of severe disease include flexion deformities or joint instability. Quadriceps weakness represents an early modifiable risk factor for knee OA progression, particularly in women,[42,43] and in late stages of disease, it may be apparent as muscle atrophy.[44,45] Alterations in proprioception and vibratory sense have been demonstrated in association with knee OA, although the relation of these factors to progression and pain is still unclear.[46,47] Patellofemoral OA may be more common than tibiofemoral OA[48] and can strongly contribute to pain and disability at the knee, but it is often overlooked.[49] OA of the patellofemoral joint is characterized by crepitus and pain with ascending or descending stairs and is often located anteriorly. It can be seen in isolation or in association with tibiofemoral OA.[48] The relation between patellofemoral OA and commonly seen patellofemoral pain disorders in younger individuals remains to be elucidated.[50]

### Joint-Specific Symptoms and Signs: Hip

OA of the hip can present with groin pain, which is fairly specific,[51] but it may be described more vaguely as pain in the thigh, buttock, low back, and even in the ipsilateral knee. Therefore it is important to assess for other causes of pain in the "hip," including spinal pain (e.g., lumbar disk degeneration, spinal stenosis, facet joint OA, and sacroiliac pain); trochanteric bursitis; altered gait due to knee disease; meralgia paresthetica (i.e., lateral femoral cutaneous nerve entrapment); thigh claudication from vascular causes; or even intrapelvic causes. It is also important to consider other causes of hip and groin pain such as occult femoral neck fracture or avascular necrosis. People affected by hip OA have limitations in walking, bending, and transferring, as well as stair climbing. Internal rotation of the affected hip is often limited and can be quite painful, even in early-stage disease; it is often evident to the patient because of through difficulty in putting on socks, tying shoes, or trimming toenails. Visible deformity, hip flexion contracture, or severe limitations of range of motion are indicators of more advanced disease, which may also be associated with shortening of the affected limb as a result of superior migration of the femoral head. In young individuals presenting with groin pain that is worsened by sitting and who have pain and limitation when internally rotating and adducting the hip in the flexed position, femoroacetabular impingement is a consideration.[52]

### Joint-Specific Symptoms and Signs: Hand

The hands often provide the first clue to a diagnosis of OA. As previously mentioned, evident bony enlargement of the DIP joints (Heberden's nodes) and PIP joints (Bouchard's nodes) can be appreciated (Figure 99-2). These nodes may be acutely inflamed with warmth and tenderness or may be bland, hard enlargements and are often more marked in the dominant hand. Some patients, most commonly older women, have erosive OA characterized by episodic inflammation, pain, and swelling. It remains a matter of debate whether this type of OA is part of the continuum or is a separate disease entity.[53,54] OA involvement of the first CMC joint is particularly problematic and can lead to significant pain, limitations in functionality of the hand, and reduced grip strength.[55,56] CMC squaring, representing deformity of the joint as a result of osteophyte formation and joint space narrowing, can be seen on examination. Bilateral involvement of multiple joints is frequent, both within joint groups (multiple PIPs) and across joint groups (both DIPs and PIPs). Metacarpophalangeal joints are

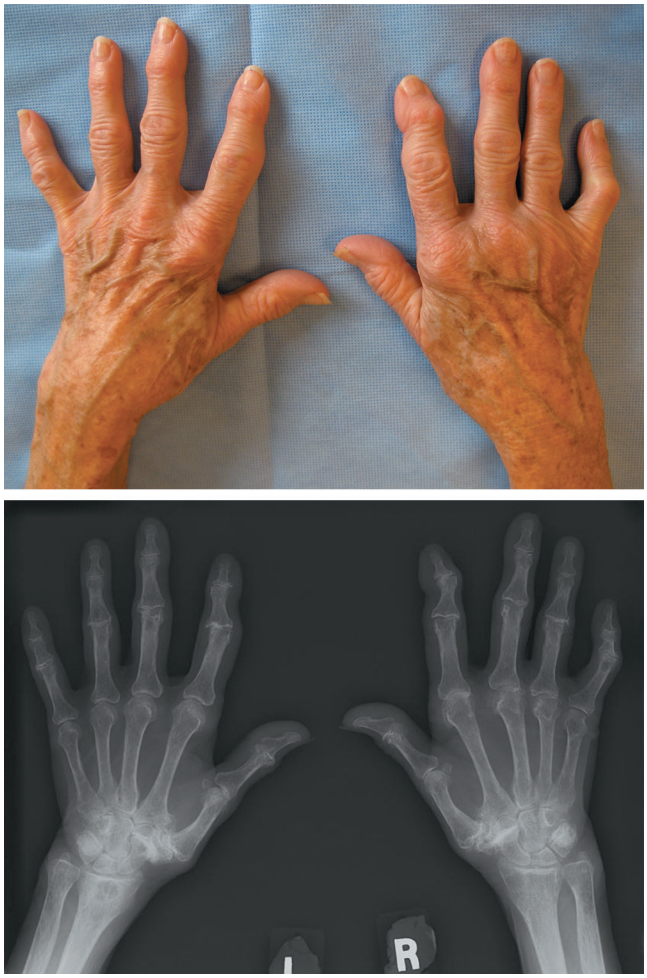

**Figure 99-2** The hands of a 79-year-old woman showing clinical *(top)* and radiographic *(bottom)* features of osteoarthritis (OA). This patient has Heberden's and Bouchard's nodes of multiple digits; radiographs show osteophytes, joint space narrowing, and cysts typical of OA, as well as "gull-wing" deformities at the third proximal interphalangeal joints suggestive of erosive OA.

affected more commonly than previously recognized,[57] although prominent involvement of these joints should prompt consideration of inflammatory/crystalline arthropathies or secondary causes of OA, such as hemochromatosis.[58] Soft tissue conditions such as De Quervain's tenosynovitis should be considered because they are associated with hand OA, can mimic or aggravate symptoms, and are amenable to conservative management.

## Joint-Specific Symptoms and Signs: Spine

Facet joint OA is prevalent among older adults. In one study, it was found that cervical spine facet joint OA and lumbar spine facet joint OA were present in 57% and 89%, respectively, of community-living adults older than 65 years.[59] The association between facet joint OA and back pain has been controversial, although a recent study using CT assessments of lumbar facet joint OA identified associations between severe facet joint OA and back pain, with an odds ratio greater than 2; individuals with multiple affected facet joints were also more likely to have back pain.[60] Facet joint OA is associated with OA of other joint sites, including the knees and hands.[19]

Osteophytosis of the spine is nearly ubiquitous in older individuals, although it is often asymptomatic.[61] Lumbar disk degeneration (LDD), characterized by disk space narrowing, end-plate sclerosis, and herniation, is often seen in association with radiographic osteophytosis,[62] although the relationship between LDD and OA of other joint sites remains controversial. [19,63]

Symptomatically, these findings can be associated with radiculopathy, a pathologic process of the nerve roots most commonly seen in older patients as a consequence of hypertrophied facet joints or uncovertebral joints, disk protrusion, osteophytosis of the vertebral body, or a combination of these features.[64,65] Cervical radiculopathy most commonly involves the seventh cervical nerve root and is caused by degenerative changes at the C6-C7 level.[64] Patients may present with pain/numbness in the shoulders, triceps area, forearm, and dorsal long finger, and triceps weakness or loss of reflex may be present.[64] Lumbosacral radiculopathy, frequently due to disk degeneration (particularly at lower lumbar levels), presents with radiating back pain that is usually exacerbated by leaning forward, sitting, or straining and is relieved by lying down.[65] Specific clinical presentation varies by level, with the lower levels more commonly affected. L4 radiculopathy can result in medial lower leg sensory changes, weak knee extension and hip adduction, and potentially reduced knee jerk.[65] At L5, foot drop and sensory symptoms of the anterolateral leg and dorsal foot may be seen, whereas S1 radiculopathy is characterized by weakness of plantar flexion, knee flexion, and hip extension with reduced ankle jerk.[65] Cauda equina syndrome, a medical emergency, occurs as a result of compression of the lower lumbar and sacral nerve roots by a central disk herniation, commonly at L4-L5. This syndrome results in bowel and bladder dysfunction, saddle anesthesia, and leg weakness.[65]

Diffuse idiopathic skeletal hyperostosis, or DISH, is characterized by exuberant osteophytosis and calcification of spinal ligaments and entheses, leading to an appearance likened to flowing candle wax.[66] People with DISH can be asymptomatic and may be identified only by radiographic appearance, or they can present in a fashion similar to that of individuals with OA or LDD. Large anterior cervical spine osteophytes, which are more often seen in DISH but are possible in LDD, can cause dysphagia as a result of compression of the esophagus.[67]

## Joint-Specific Symptoms and Signs: Shoulder

The shoulder is a common source of pain in people with OA, although the symptoms are more often due to osteophytosis and narrowing of the acromioclavicular and/or sternoclavicular joints than of the glenohumeral joint itself. Other maladies common in older adults, such as subacromial bursitis, rotator cuff disease, and adhesive capsulitis, should be assessed. Rotator cuff damage, in particular, can predispose to glenohumeral OA. Disease at the cervical spine can present as pain in the shoulder region, and thus the shoulder evaluation should include an assessment of the cervical spine. Milwaukee shoulder syndrome[68] is a rare

destructive arthropathy of the glenohumeral joint associated with large effusions, which is bilateral in 60% of cases and also affects the knees in 50% of cases.[69] Radiologically, periarticular calcifications and cuff rupture may be seen, and synovial fluid examination often reveals high red blood cell content and basic calcium crystals (particularly if Alizarin red staining is used).[69]

## Joint-Specific Symptoms and Signs: Other Joints

OA of the foot has been largely neglected in the literature to date. The foot joints most commonly affected by OA include the talocalcaneal joint, talonavicular joint, calcaneocuboid joint, metatarsocuneiform joint, and first metatarsophalangeal (MTP) joint; these joints can be affected by erosive OA as well.[70] OA of the first MTP joint is characterized by pain and hallux valgus (bunion) deformity and has radiographic features (e.g., joint space narrowing and osteophytosis) similar to OA at other joints. Loss of function at the first MTP joint as a result of ankylosis (hallux rigidus) can lead to altered gait. Ankle OA likely occurs more frequently than previously thought and may be due to biomechanical alterations from OA at other joints, in addition to accepted post-traumatic and injury-related etiologies.[17] Elbow OA is rare and may be the result of trauma, vibration damage, or other entities such as pseudogout. Temporomandibular joint OA is largely ignored in the orthopedic and rheumatologic literature but is well researched in the dental literature; it results in pain, clicking, locking, decreased range of motion, and crepitus of the joint, much like in other joints affected by OA.[71]

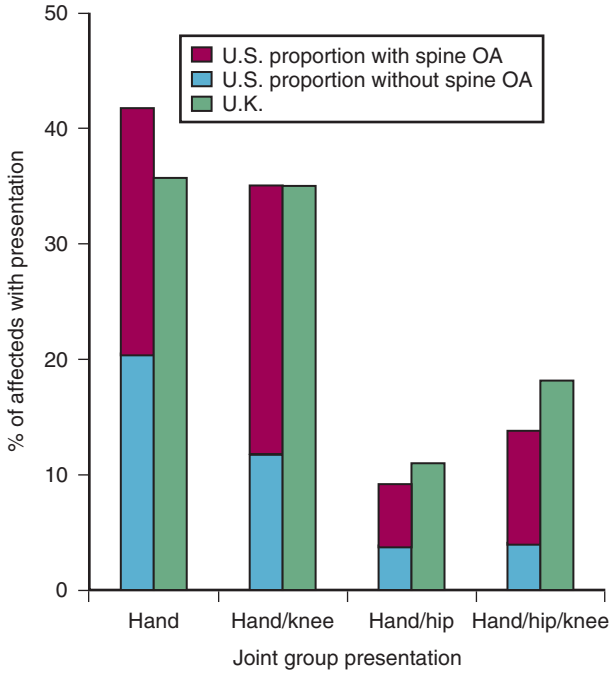

**Figure 99-3** The frequency of multiple joint involvement with radiographic osteoarthritis (OA) in the Genetics of Generalized Osteoarthritis Study. The frequencies of radiographic OA at various sites and sites in combination are shown for the United States (U.S.) in *blue*. For the United Kingdom (U.K.) they are shown in *green* for the 1963 participants meeting specified hand radiographic OA criteria. The groups represented are mutually exclusive. The frequency of spine OA (only assessed at U.S. sites) in combination with these phenotypes is indicated by the *red bars. (Modified from Kraus VB, Jordan JM, Doherty M, et al: The Genetics of Generalized Osteoarthritis [GOGO] study: study design and evaluation of osteoarthritis phenotypes.* Osteoarthritis Cartilage *15:120–127, 2007.)*

## Polyarticular Osteoarthritis

For more than 100 years, it has been recognized that OA can simultaneously occur in multiple joint sites.[72] Although the term *generalized* OA (GOA) has been used to describe this disease entity, there is no universally understood or accepted definition of what constitutes GOA (Figure 99-3).[73] In 1952, Kellgren and Moore provided the first clinical description of GOA, involving primarily Heberden's nodes and the CMC joints, with the spine, knees, hips, and feet involved in descending frequency.[74] Later studies have defined GOA as more than three or more than five joint sites affected,[75] affected joint counts,[76,77] multiple hand joint involvement,[78] nodal hand OA with other joint involvement,[57] or summed scores of OA across multiple joints.[79,80] It remains unclear which joints should be included in such definitions, and particularly whether lumbar disk degeneration and hip OA are part of the same disease entity as other joints. Clinically, it is important to recognize that a patient with OA in one joint is likely to have involvement at other sites and to assess the impact of that person's overall OA burden on their functional status, rather than focusing on a single joint.

## Nodal Osteoarthritis and Genetics

Nodal OA, which was described by Heberden in the 1800s, is a clinically apparent phenotype affecting 58% of U.S. adults older than 60 years in NHANES III.[81] Increasing numbers of nodes are associated with greater pain and functional limitation and reduced patient satisfaction.[53] The inheritance patterns of nodal OA have been studied in some detail, beginning with Stecher in the 1940s.[82] Using pedigrees and modes of mendelian inheritance, he determined that idiopathic Heberden's nodes "depend upon a single autosomal gene sex influenced to be dominant in females and recessive in males."[82] This method of inheritance was supported by an independent study 6 decades later.[83] A genetic predisposition to Heberden's nodes was also supported in a twin study in which the intraclass correlation among monozygotic twins was much higher than that among dizygotic twins (0.49 and 0.24, respectively; $P = 0.02$).[84] A microsatellite analysis identified an association between nodal OA and chromosome 2q.[85] Evidence exists of genetic anticipation in nodal OA as well, with both nodal symptom onset and associated large joint OA occurrence at significantly younger ages in offspring compared with parents (during the 40s in offspring compared with the 60s in parents).[86] More recently, in 2006, a genome-wide linkage study identified several loci associated specifically with nodal OA.[87] In another study, differences in risk factor associations were apparent in individuals with nodal OA who were undergoing total joint replacement (as a marker of severe large joint OA), compared with individuals who had non-nodal OA.[41] These investigators found that the

association between age and joint replacement was significantly stronger in nodal versus non-nodal OA; a positive association between female sex and joint replacement was apparent only for people with nodal OA; body mass index demonstrated a stronger association among people with non-nodal compared with nodal OA; and people with the nodal phenotype had a higher prevalence of OA at more than one joint.[88] Therefore nodal OA is a clinically apparent and useful phenotype that is associated with multiple joint OA involvement and likely has specific genetic risk factors.

# DIAGNOSTIC TESTING

## Diagnostic Approach

OA is diagnosed clinically, and laboratory testing is rarely required. Similarly, if the diagnosis is clear on the basis of history and clinical findings, radiographs often are not required. The purpose of additional diagnostic testing in OA is primarily to exclude potentially treatable underlying conditions. Depending on the patient's presentation, the diagnosis may be straightforward, or the differential diagnosis may include inflammatory arthropathies, such as rheumatoid arthritis, crystalline arthropathies (particularly calcium pyrophosphate crystal deposition disease), spondyloarthropathies, or a variety of other inflammatory conditions. Particularly in the case of erosive/inflammatory OA, there may be significant clinical and radiographic overlap with psoriatic arthritis, requiring further evaluation. If the presentation is of a monoarthritis, evaluation for infectious causes should be performed. Finally, trauma and other mechanical disorders (e.g., tendon or ligament injury and meniscal tears) may be seen prior to, as a part of, or subsequent to the development of OA in a given joint.

## Laboratory Testing

There is rarely an indication for testing rheumatoid factor or anti-nuclear antibodies or for performing other serologic studies in the setting of clinically suspected OA; such tests should be reserved for patients with findings suggestive of an inflammatory arthropathy. A complete blood cell count, chemistry panel, including glucose, creatinine, and liver function tests, should be obtained before initiation of pharmacologic therapy for OA, especially in older individuals with comorbid medical conditions, because of an increased risk of adverse events in this population. In cases in which there is prominent involvement of the metacarpophalangeal (MCP) joints, evaluation for hypothyroidism and hemochromatosis may be warranted.

### Synovial Fluid

The synovial fluid in people with OA is typically normal or mildly inflammatory, appearing clear and colorless to slightly yellowish. The leukocyte cell count is typically less than or equal to 2000 cells/mm$^3$ (<2 cells seen across 10 high-power fields).[89] Fluid is often obtained in the course of an intra-articular injection for a symptomatic joint, although diagnostic aspiration may also be performed in the setting of an effusion. Concomitant calcium pyrophosphate crystal disease can be identified, although other calcium crystals, or hydroxyapatite, are not seen on routine preparations.

### Molecular Biomarkers

Quantitative determination of the products of cartilage and bone metabolism has provided several putative biomarkers of OA pathophysiology. For example, one such biomarker, urinary C-telopeptide fragments of type II collagen (u-CTXII), is associated with the occurrence and progression of radiographic OA, independent of other risk factors.[80] Such biomarkers, obtained from serum, urine, or synovial fluid, eventually may provide a method for early diagnosis and monitoring of treatment effect, although currently they are used primarily in research. Interested readers are referred to a comprehensive review from 2010,[90] a 2014 overview of the 12 biomarkers with the most supportive evidence of OA associations to date,[91] and Chapter 98 in this book for additional details.

## Imaging: Conventional Radiography and General Considerations

Conventional radiography is widely available in clinical settings and is relatively inexpensive, making this modality useful to confirm the diagnosis of OA and exclude others, primarily when there is clinical uncertainty regarding the diagnosis, when the joint involved is atypical, or when evidence suggests other diagnoses such as inflammatory arthritis, fractures, Paget's disease, osteonecrosis, infection, or malignancy. Radiographs of joints affected by OA typically show osteophytes, joint space narrowing, sclerosis, and cysts of subchondral bone, which will be described qualitatively on clinical radiographs.

For research purposes, semiquantitative and quantitative assessments are used. The semiquantitative Kellgren-Lawrence (KL) grading system remains the most commonly used for research purposes.[92] KL grades range from 0 (no osteophytes or joint space narrowing) to 4 (severe joint space narrowing with subchondral sclerosis); a grade of 2 is generally considered diagnostic of OA. The KL system has several limitations, including variable definitions in the literature[93] and the categorization of all "definite" joint space narrowing as KL grade 3, thus reducing sensitivity to change, although modifications have been suggested to address this issue.[94] Additionally, identification of joint space narrowing on radiographs is not a specific finding indicative of cartilage loss but can also be reflective of meniscal disease. Other semiquantitative grading systems, such as the Osteoarthritis Research Society International (OARSI) grading system,[95] view osteophytes and joint space narrowing separately and assign grades for these specific OA features individually for various joint compartments (Figure 99-4). The choice of grading system depends on the goal of the study and the joint site of interest. Quantitative joint space width, on the other hand, is a direct measure of the space between the femur and tibia that is performed either manually or in a semi- or fully automated manner. Quantitative joint space width is commonly assessed as the minimum joint space width, but it has also been explored at fixed locations; the latter method has been shown to be comparable to MRI in the detection of OA progression.[96]

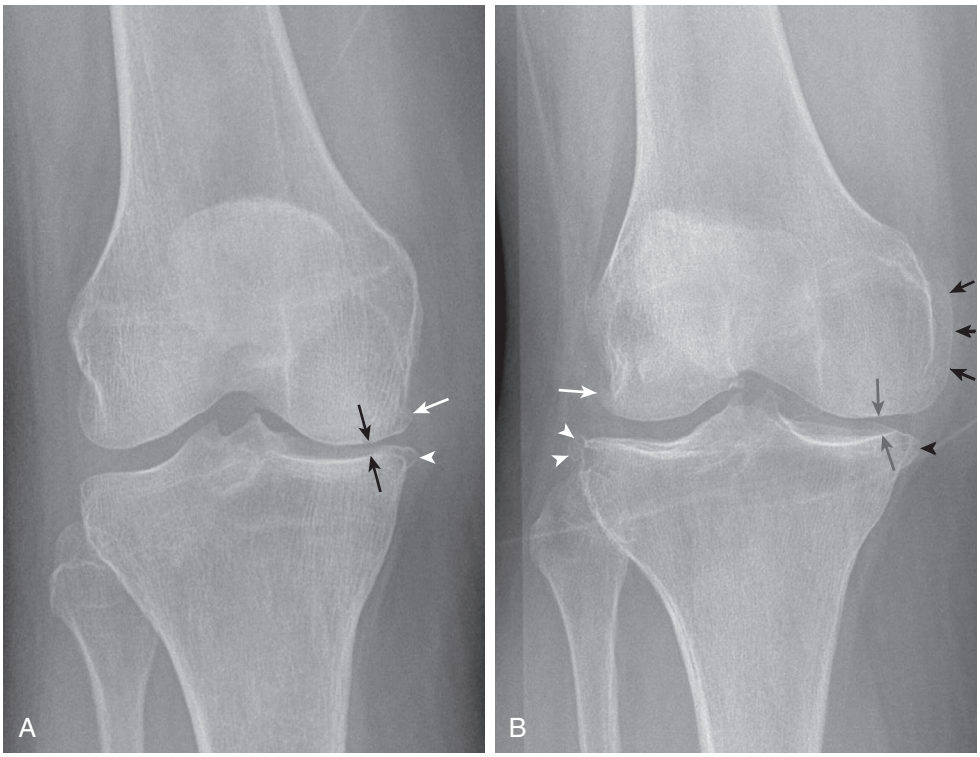

**Figure 99-4** Examples of semiquantitative radiographic assessment with use of the Kellgren-Lawrence and Osteoarthritis Research Society International (OARSI) grading schemes. **A,** Kellgren-Lawrence grade 3. No lateral femoral and tibial osteophytes are seen (OARSI grade 0). A medial femoral osteophyte: OARSI grade 1 *(white arrow);* a medial tibial osteophyte: OARSI grade 2 *(white arrowhead);* lateral tibiofemoral joint-space width: OARSI grade 0; and medial tibiofemoral joint-space narrowing: OARSI grade 2 *(black arrows)* are depicted. **B,** Kellgren-Lawrence grade 2. A lateral femoral osteophyte: OARSI grade 2 *(white arrow);* a lateral tibial osteophyte: OARSI grade 2 *(white arrowheads);* a medial femoral osteophyte: OARSI grade 3 *(short black arrows);* a medial tibial osteophyte: OARSI grade 2 *(black arrowhead);* a normal lateral tibiofemoral joint-space width: OARSI grade 0; and medial tibiofemoral joint-space width: OARSI grade 1 *(long black arrows)* are shown. *(From Guermazi A, Hunter DJ, Roemer FW: Plain radiography and magnetic resonance imaging diagnostics in osteoarthritis: validated staging and scoring.* J Bone Joint Surg Am *91[Suppl 1]:54–62, 2009.)*

## Imaging: Conventional Radiography of Specific Joints

Imaging of the knees should be bilateral while the patient is weight bearing, and for clinical purposes, it is generally anteroposterior (AP). Posteroanterior views in fixed flexion are commonly used for research, and lateral views may be necessary in some circumstances.[97] Sunrise views are needed to fully assess the patellofemoral joint. Alignment, although best determined from full-limb views, can be estimated from routine knee films.[98] An AP pelvis view should be obtained to assess hip OA and can be either supine or weight bearing. Additional views such as frog-leg, lateral, or Dunn views may be indicated for specific hip disease or to assess for femoroacetabular impingement or congenital abnormalities. An atrophic subtype of hip OA, characterized by joint space narrowing with either mild or absent osteophytosis, has been described,[99] and alternative radiographic definitions for hip OA (other than KL grading) have been proposed and used in research to address this issue.[100] For hand OA, a posteroanterior view of both hands, including the wrists, will reveal the characteristic features of OA. If there is an erosive component to hand OA, radiographs may demonstrate central erosions and "gull-wing" deformities of the interphalangeal joints (see Figure 99-2). Marked destructive changes at the DIP joints may indicate another inflammatory disorder such as psoriatic arthritis or, rarely, multicentric reticulohistiocytosis. Prominent involvement of the MCP joints may indicate a metabolic process such as hemochromatosis or calcium pyrophosphate deposition disease. Conventional radiography of the cervical and/or lumbar spine can show facet OA, disk space narrowing, and osteophytosis.

## Imaging: Advanced Modalities

Several advanced imaging modalities such as MRI, ultrasound, CT, and positron-emission tomography (PET) scans have been used in OA research, although with the exception of ultrasound, these generally specialized, expensive examinations are not indicated in routine clinical practice. A brief summary of these modalities in OA is provided in the following sections.

### Magnetic Resonance Imaging

MRI is the most well-studied advanced imaging modality in OA. Unlike radiography, it allows visualization of all joint tissues, including cartilage, menisci, ligament/tendon, synovium, effusions, and bone marrow simultaneously, although arthroscopy remains the gold standard for joint tissue assessment.[94] An MRI-based definition of tibiofemoral OA has been proposed that requires either the presence of both definite osteophytes and full-thickness cartilage loss or one of these and one of the following features: a

subchondral bone marrow lesion or cyst, meniscal disease (subluxation, maceration, or horizontal tear), partial-thickness cartilage loss, or bone attrition.[9]

Semiquantitative scoring, which can be performed using conventional acquisition techniques, is frequently used to evaluate a number of OA features simultaneously, such as the articular cartilage, meniscus, ligaments, bone marrow, synovitis, and joint effusion (Figure 99-5).[101] Several scoring systems are publicly available. Whole Organ Magnetic Resonance Imaging Score (WORMS), the oldest and most widely used semiquantitative system for MRI scoring in OA, utilizes a subregional approach to scoring of features, including cartilage, bone marrow lesions (BMLs), subchondral cysts, bone attrition, effusion, synovitis, osteophytes, meniscal tears, and cruciate and collateral ligaments.[101] The Knee Osteoarthritis Scoring System (KOSS) is similar but counts more individual lesions and includes size assessments. The Boston Leeds Osteoarthritis Knee Score (BLOKS) varies slightly in subregion definition and individually scores BMLs. The MRI Osteoarthritis Knee Score (MOAKS), which was more recently developed[102] as a response to some of the shortcomings of the other systems, refines scoring of BMLs and meniscal disease.[101] Semiquantitative scores are also available that focus on only one feature, such as cartilage or synovitis.

Overall, semiquantitative methods for knee OA are adequately responsive to change and are reliable. At the knee, semiquantitatively assessed BMLs, joint effusion, and synovitis are associated with pain, and development of knee pain is associated with increasing BML score over time.[101] Progression of cartilage loss is associated with semiquantitatively assessed meniscal damage/malposition, prevalent cartilage damage, BMLs, and effusion.[101] A recent study using MOAKS and data from the Osteoarthritis Initiative found that, among 849 individuals with no radiographic evidence of knee OA at baseline (bilateral KL grade = 0; one-third of whom had baseline frequent knee symptoms), the majority had cartilage damage (76%) and bone marrow lesions (61%) as identified by MRI, and these lesions were associated with prevalent and incident knee symptoms.[103] Semiquantitative MRI scoring has also been utilized at the hip, hand, shoulder, and spine, although to a much lesser extent than for knee OA.[101]

Quantitative assessment of MRI involves quantification of specific tissue characteristics such as thickness and volume of cartilage or size and volume of BMLs. These techniques are time and labor intensive but provide greater sensitivity to change compared with semiquantitative scoring.[101] Quantitatively assessed cartilage thickness and denuded areas of subchondral bone predict clinical outcomes such as joint replacement.[94]

Compositional imaging techniques, which allow visualization of anatomy and biochemical properties as well, have been used in the setting of very early stage disease prior to obvious structural alterations. Techniques include delayed gadolinium-enhanced MRI of cartilage (dGEMRIC) and T1 rho, which can visualize changes in glycosaminoglycan concentrations, and T2 mapping, which reflects variation in collagen orientation and cartilage hydration status.[94] Alterations in compositional MRI have been reported in exercise/joint loading and weight change,[94] with a suggestion of possible associations with disease progression.[104]

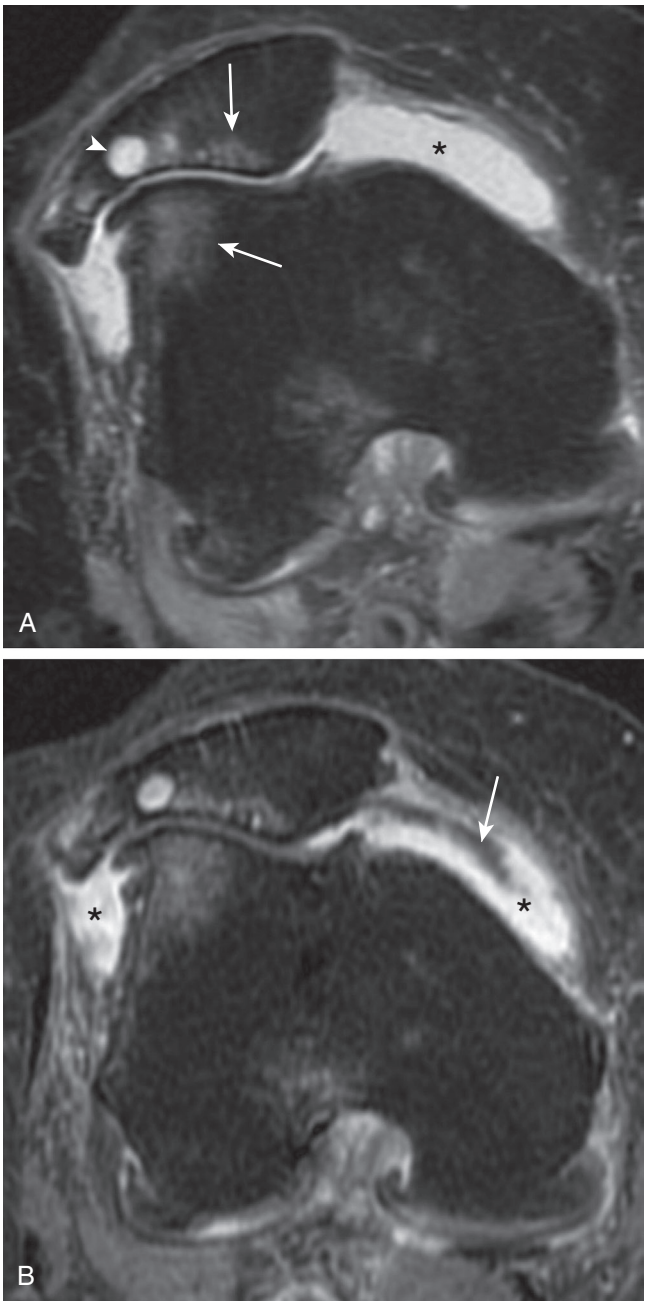

**Figure 99-5** Visualization of synovitis using nonenhanced and contrast-enhanced MRI. **A,** An axial proton-density–weighted fat-saturated image shows marked hyperintensity within the joint cavity, suggesting severe joint effusion *(asterisk)*. In addition, a large subchondral cyst is present in the lateral facet of the patella *(arrowhead)* and diffuse bone marrow edema is present in the lateral patella and trochlea *(arrows)*. **B,** An axial T1-weighted fat-saturated image after administration of contrast material clearly visualizes severe synovial thickening depicted as contrast enhancement *(asterisks)*. The *arrow* points to true amount of effusion, which is only discrete and visualized as linear hypointensity within the joint cavity. *(From Roemer FW, Eckstein F, Hayashi D, et al: The role of imaging in osteoarthritis.* Best Pract Clin Rheumatol *28:31–60, 2014.)*

## Ultrasound

Ultrasound is a point-of-care modality that can be used directly by trained providers (e.g., rheumatologists, radiologists, and orthopedists) to assess joint disease in patients. Its relatively low cost, safety (because it does not entail use of

radiation or contrast agents), short examination duration, convenience (it can be performed in the provider's office), and noninvasive nature make it an attractive OA assessment method. It has several advantages compared with conventional radiography, including lack of radiation, ability to obtain numerous views of a given joint, and ability to assess soft tissues and inflammation. Limitations include the inability of sonography to penetrate the bony cortex, which prevents assessment of BMLs or deeper aspects of the joints. A recent study using data from 311 community-dwelling people aged 61 to 63 years participating in the Newcastle Thousand Families birth cohort found a high prevalence of ultrasound osteophytosis at the DIP (70%), index PIP (23%), index MCP (10%), thumb base CMC joints (41%), knees (30%), and hips (41%), whereas knee effusion was present in 20% to 24%.[105]

For knee OA, ultrasound is more sensitive than clinical examination and is comparable with MRI in the detection of synovitis, which correlates with pain.[106] Inter-rater reliability for a variety of features of knee OA (e.g., meniscal extrusion, infrapatellar bursitis, effusion, popliteal cyst, and cartilage thickness) has been reported as moderate to good (κ values 0.5 to 0.8), although agreement on synovial hypertrophy was poor.[107] Measurement of articular cartilage by ultrasound was accurate and reproducible compared with direct anatomic measurements.[108,109] ultrasound-guided intra-articular injections also can be beneficial; a systematic review of 23 publications found that injections at the superomedial patellar, medial midpatellar, superolateral patellar, and lateral suprapatellar sites were more accurate with image guidance rather than without image guidance.[110] Ultrasound guidance also allows direct aspiration/injection of popliteal cysts for symptomatic relief.

In the hand, ultrasound is more sensitive than radiographs for the detection of erosions, osteophytes, and joint space narrowing, although estimates of ultrasound-detected cartilage thickness are correlated with radiographic determinations.[111] Generally, good agreement is found between ultrasound and MRI for structural features and inflammation.[111]

### Computed Tomography

CT is the best modality for assessment of cortical bone and soft tissue calcifications. It is also the main technique used for assessment of facet joint OA.[112] CT arthrography is the most accurate method for the evaluation of articular cartilage surface damage because of high contrast between cartilage, a contrast agent, and bone using this modality, although expense, invasiveness, and radiation exposure limit its use.[112]

### Nuclear Medicine

Bone scans (technetium 99m hydroxymethane diphosphonate scintigraphy) provide a full-body image in one test, allowing location of the site of inflammation in patients with complex symptomatology. Bone scans have been used as a measure of whole-body OA burden for evaluation of systemic biomarkers.[113] PET, most often using 18F-fluorodeoxyglucose, can detect synovitis, BMLs, and other sources of increased metabolic activity in aging and OA joints, and these findings have been associated with pain.[114,115] Limitations include cost, limited availability, poor anatomic resolution, use of ionizing radiation, and invasiveness (because of the injection of the radiopharmaceutical agent); small-parts scanners are in development and may improve feasibility for musculoskeletal imaging.[94]

## OUTCOME

### Pain and Functional Status Assessment

Numerous validated tools for assessing functional status in OA are available and widely used in research settings. As the focus on quality of care increases, these tools will likely be incorporated more frequently into clinical practice.

### Self-Reported Measures of Pain and Function

Questionnaire-based measures of pain and functional status provide rapid and repeatable patient-based assessments that can be monitored over time and for treatment response. Numerous well-studied, validated, and reliable measures are available for this purpose. For overall function, the Stanford Health Assessment Questionnaire (HAQ) disability index is often used, although it is not disease specific. For OA-specific lower extremity pain and function, the Western Ontario and McMaster Universities Arthritis Index (WOMAC; Table 99-4) is the most frequently used

**TABLE 99-4** Western Ontario and McMaster Universities Arthritis Index

| |
|---|
| **Pain Subscale** |
| How much pain do you have… |
| Walking on a flat surface? |
| Going up or down stairs? |
| At night while in bed? |
| Sitting or lying? |
| Standing upright? |
| **Stiffness Subscale** |
| How severe is your stiffness… |
| After first waking in the morning? |
| After sitting, lying down, or resting later in the day? |
| **Function Subscale** |
| What degree of difficulty do you have with… |
| Descending stairs? |
| Ascending stairs? |
| Rising from sitting? |
| Standing? |
| Bending to floor? |
| Walking on a flat surface? |
| Getting in or out of a car? |

Modified from Bellamy N, Buchanan WW, Goldsmith CH, et al: Validation study of WOMAC: a health status instrument for measuring clinically important patient relevant outcomes to anti-rheumatic drug therapy in patients with osteoarthritis of the hip or knee. *J Rheumatol* 15:1833–1840, 1988.

tool, although joint-specific measures such as the Hip Disability and Osteoarthritis Outcome Score (HOOS) and Knee Injury and Osteoarthritis Outcome Score (KOOS) are also validated and are often used in research. Measures are available for other joint sites as well, such as the Australian/Canadian Hand Osteoarthritis Index (AUSCAN) and Functional Index for Hand Osteoarthritis (FIHOA) for hand-specific function; Disabilities of the Arm, Shoulder, and Hand Questionnaire (DASH) for the upper extremity; and the Roland-Morris Disability Questionnaire and Oswestry Disability Index for low back disorders, among others. Various clinically important features of these measures have been established, such as responsiveness and minimal clinically important differences, all of which have been reviewed.[116]

### Performance-Based Assessment

Results on standardized performance-based tests, such as determination of walking speed and time to stand from a chair five times unassisted, have been shown to correlate with the severity and number of affected joints in OA.[117,118] The Osteoarthritis Research Society International recently provided guidelines for appropriate performance-based tests for hip or knee OA, which include a 30-second chair-stand test, 40-m fast-paced walk test, stair-climb test, timed up-and-go test, and 6-minute walk test, with the first three tests as a minimal core set of measures.[119]

## Quality of Life

OA is a chronic, progressive, and often debilitating condition, and thus assessment of quality of life is an important outcome for monitoring and treatment. Generic measures of quality of life, such as the Medical Outcomes Study Short Forms (SF-36, SF-12, and SF-6D) and Assessment of Quality of Life (AQoL), are commonly used.[116] The HOOS and KOOS previously discussed include quality-of-life domains specific to knee and hip OA.[116] The Osteoarthritis Knee and Hip Quality of Life (OAKHQOL) has been validated for this purpose.[120]

## Time to Total Joint Replacement

Total joint replacement is a "hard" endpoint in OA, but its use as an outcome measure is hampered by the prolonged time needed for assessment, the large number of patients and events required, and a variety of factors affecting an individual patient's decision to undergo this procedure, including health care system issues, procedure availability, comorbid conditions, ability to rehabilitate the joint, and patient/provider preference.[121] To date, efforts have not been successful to identify a composite index that would consider pain, functional disability, and structural degradation; that would define the "need for total joint replacement"; and that could be used as an outcome measure.[122]

## Responder Criteria

In some cases, it is more useful to categorize individuals as responders or nonresponders to treatments, given the shortcomings of outcomes based solely on imaging or self-report, particularly for clinical trials. The Outcome Measures in Rheumatology (OMERACT)-OARSI responder criteria provide a composite assessment, including threshold levels of percentage improvements in pain and function, as well as required thresholds of absolute change to define response and no response that are applicable in a variety of settings.[123]

## Mortality in Osteoarthritis

Moderate evidence indicates increased mortality in individuals with OA compared with the general population.[124] The apparent modestly increased mortality risk, determined through a review of nine studies, primarily appears to be due to cardiovascular and gastrointestinal causes. One study showed an increased mortality risk with increasing numbers of joint groups affected by OA, as well as reduced survival in individuals with hand, bilateral knee, or cervical spine involvement, but not in those with OA of the hip, foot, or lumbar spine.[125] Contributors to increased mortality risk include a combination of reduced physical activity among individuals with OA, comorbid conditions, and/or adverse medication effects such as are seen with acetaminophen and nonsteroidal anti-inflammatory drugs.[124] A recent study of Canadians aged 55 years and older with moderate to severe symptomatic hip or knee OA found that poorer WOMAC function scores and walking disability were associated with higher all-cause mortality in this population.[126]

# CONCLUSION

OA is a highly prevalent and debilitating condition with increasing prevalence as a result of the aging of our society and the ongoing obesity epidemic. OA is readily recognized on clinical grounds, although further diagnostic testing and imaging are indicated in some cases to assess for potentially treatable underlying conditions. Pain is the most common reason for a person with OA to seek medical advice, and examination often reveals loss of function. Assessment of the patient's pain symptoms and functional limitations, in the framework of that person's goals, is necessary to formulate an appropriate plan of care in the absence of disease-modifying medications. Current research in OA, in addition to ongoing efforts in both pharmacologic and nonpharmacologic therapeutic development, is focused on optimizing incident case and progression definitions and understanding the whole-body burden of OA.

CHAPTER 100

# Treatment of Osteoarthritis

David T. Felson

**KEY POINTS**

- Treatment approaches for painful osteoarthritis (OA) should take into account causes, frequency, and severity of pain.
- Nonpharmacologic treatments such as activity modification, education, and exercise should be a part of treatment for everyone with OA.
- Many different types of exercise can be effective for knee and hip OA. Patient adherence to exercise is the main challenge.
- Nonsteroidal anti-inflammatory drugs are moderately effective in OA, more than acetaminophen, and should be started either as topical preparations or on an as-needed basis.
- Intra-articular steroid injections are highly effective, especially within a few weeks after the injection.
- Evidence does not support the efficacy of glucosamine, chondroitin, or both to treat OA, and the evidence to support hyaluronic acid preparations is not conclusive.
- There are many unproven remedies used by patients.
- Knee and hip joint replacements are highly effective surgeries and should be offered to patients with advanced osteoarthritis who have nocturnal joint pain or pain with rest, or patients in whom pain causes work and functional impairment.

Osteoarthritis (OA) is the most common type of arthritis in the United States and throughout the world, and is the cause of more mobility disability than any other disease. At least 27 million people in the United States have symptomatic OA of the knee, hip, or hands. Symptomatic OA is defined as pain in the joint on most days of a recent month and radiographs that show osteoarthritis in the painful joint.[1] The number of affected individuals is rising with the aging of the population, higher rates of obesity (a major risk factor for disease), and frequent sports-related joint injuries that predispose to later disease, especially in the knee. More than 50% of those affected by painful knee or hip osteoarthritis will eventually undergo joint arthroplasty, although only after living many years with pain and functional loss.[2]

The primary symptom of OA is joint pain, and relieving this pain is the main goal of therapy. In OA, pain is primarily related to carrying out activities. For example, going up and down stairs or getting out of a chair often triggers knee pain in those with knee OA. Cooking or other manual activities can precipitate hand pain in people with hand OA.

The genesis of joint pain in OA is complicated. The joint is protected from damage by multiple overlapping physiologic systems. Among these are limits to excursion established by muscles, ligaments, and the joint capsule; smooth and coordinated muscle contraction instituted by both the muscles and nervous system–mediated spinal reflexes; and reflexes that provide instantaneous input on the position and tension of muscles across the joint. Activities probably induce joint pain because the load transmitted during these activities is beyond the physiologic capabilities of the joint to withstand. This can occur because the joint is already damaged and cannot withstand much loading—as often occurs in the osteoarthritic joint—or can occur with excess loads in a normal joint. In addition to factors affecting loading are those that lower the threshold for pain, including synovitis within the joint, a common feature of OA. Synovitis may itself be triggered by microscopic damage to cartilage and other structures within the joint, with shards of tissue released into the synovial fluid ingested by synovial lining cells, generating a secondary inflammatory response. In addition, the inflammatory milieu of OA can generate peripheral and even central nervous system changes that lead to chronic pain sensitization. Other factors, including psychological and sociocultural factors, contribute to the presence and severity of pain. Thus, many factors (Figure 100-1) including loading with activities, aberrant structure of the joint that increases focal loading (such as occurs with malalignment), synovitis, impaired muscle function and coordination, deficient proprioception, and nervous system sensitivity contribute to pain. Even psychological factors could theoretically be targeted in patients with painful OA. Pain causes a person to have difficulty carrying out functional activities, including work, household activities, shopping, laundry, and recreational pursuits.

Patients with painful OA often experience other symptoms that the physician should elicit during the initial examination and patient history. These symptoms, including giving way of the joint, could be the focus of treatment. Giving way or buckling tends to occur in patients who feel that their joints are unstable, and is a common feature of painful knee and, to a lesser extent, hip OA. Factors that increase the risk of giving way include muscle weakness and the co-occurrence of pain in multiple lower extremity joints. The physician should ask patients whether their knees or hips are unstable or give way because these symptoms may increase their risk of falling and, for some patients, may be more disabling than their pain.

Video available on the accompanying ExpertConsult website.

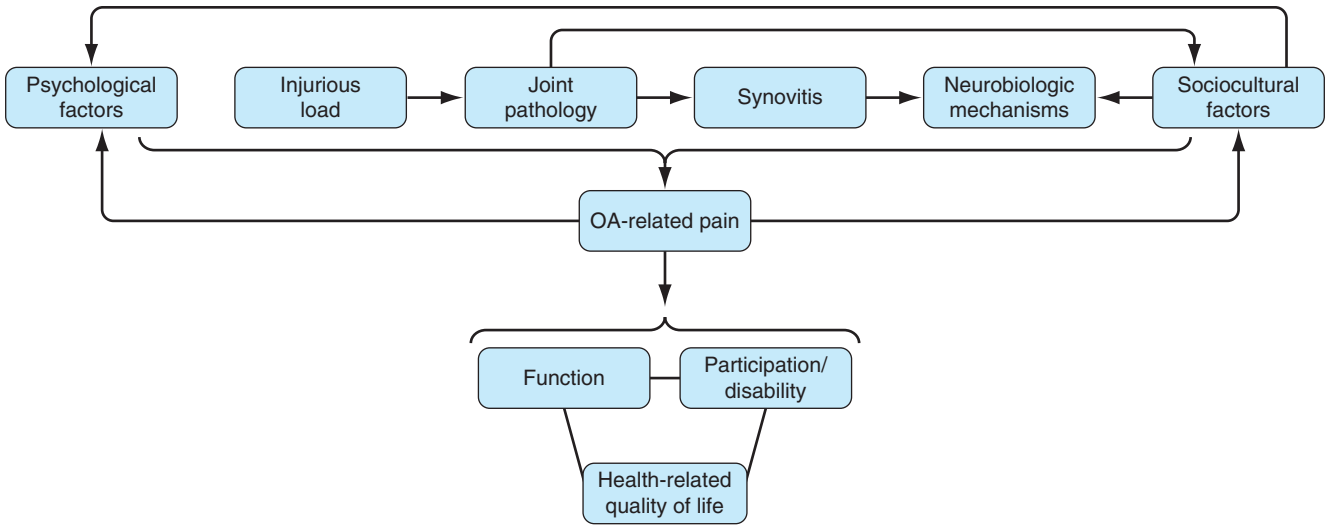

**Figure 100-1** Pathophysiology of osteoarthritis (OA)-related pain and its consequences. *(Modified from Neogi T: The epidemiology and impact of pain in osteoarthritis.* Osteoarthritis Cartilage *21[9]:1145-1153, 2013.)*

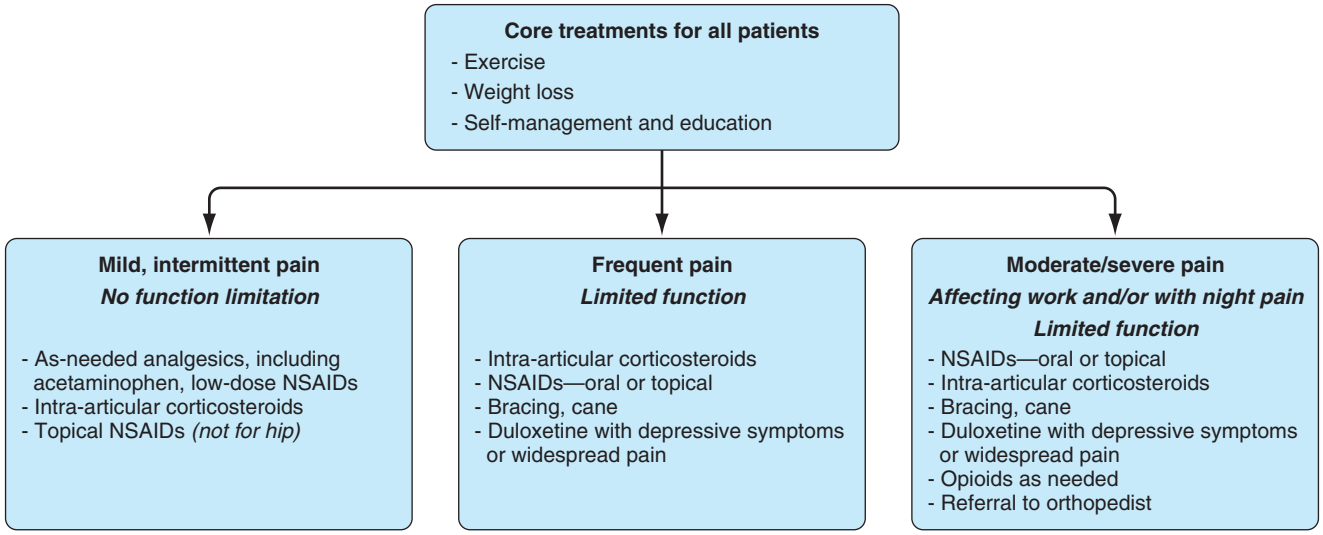

**Figure 100-2** Algorithm for management of knee and hip osteoarthritis.

The management of OA can be divided into nonpharmacologic interventions, pharmacologic interventions, and surgical options. Patients with mild or intermittent pain are likely to need only nonpharmacologic treatment, whereas those with more severe symptoms will probably require both nonpharmacologic and pharmacologic treatments (Figure 100-2).

## NONPHARMACOLOGIC TREATMENTS

### Psychosocial Interventions

As in other types of arthritis, patient education is an important first step in OA therapy. The patient should be an integral part of the decision-making team. To do this effectively, the patient should understand the nature of OA, including its natural history and treatment options. It is often reassuring for the patient to realize that OA is a common, slowly progressive ailment and is not typically as disabling or deforming as the inflammatory arthritides. A significant number of patients have already tried nonprescription medications or nutraceutical remedies before seeing a physician and will want to discuss these options. Physicians should emphasize that treatment includes nonpharmacologic and pharmacologic interventions. Organizations such as the Arthritis Foundation can be valuable sources of information geared toward patients and can provide helpful reading materials.

Some patients may develop emotional disturbances related to the pain and changes in normal daily activities that can stem from OA. These may include mood disorders such as depression or sleep disorders.

### Avoiding Painful Joint Loading

Osteoarthritic pain is activity-related, and for most affected patients, certain activities will reproducibly elicit their joint pain. The painful activities probably cause pain in part by

increasing focal loading across a damaged segment of the joint. Any of the following strategies may be successful in alleviating the pain:

- Avoiding activities that cause joint pain
- Improving the strength and conditioning of muscles that bridge the joint, to optimize their function
- Unloading the joint, either by redistributing load within the joint with a brace or a splint, or by unloading the joint during weight bearing with a cane or a crutch

The simplest effective treatment for many patients is to avoid activities that precipitate pain. For example, for the middle-aged patient whose running triggers pain in their knees, a less demanding form of weight-bearing activity may alleviate discomfort. For an older person whose daily constitutionals up and down hills cause knee pain, routing the constitutional away from hills might eliminate symptoms.

Each pound of weight increases the overall load across the knee three- to sixfold. Weight loss may have a commensurate multiplier effect, unloading both knees and hips. Obese people undergoing bariatric surgery with subsequent massive weight loss experience a marked reduction in pain.[3] Trials of modest weight loss (5 to 10 kg) suggest a moderate reduction in knee pain,[4] and the combination of exercise with weight loss appears more effective at relieving pain and reducing knee loading than weight loss alone.[5]

In hand joints affected by OA, splinting, by limiting motion, often minimizes pain for patients with involvement especially in the base of the thumb. Weight-bearing joints such as knees and hips can be unloaded by using a cane in the hand opposite to the affected joint for partial weight bearing. A physical therapist can teach the patient how to use the cane optimally, including ensuring that its height is optimal for unloading (the optimal height for a cane is with the elbow of the arm holding the cane flexed at an approximately 20-degree angle, or with the top of the cane at approximately the level of the femoral greater trochanter). Crutches or walkers can serve a similar beneficial unloading function.

## Exercise

Osteoarthritic pain in knees or hips during weight bearing results in lack of activity and poor mobility and, because OA is so common, the inactivity that results increases the risk of obesity and cardiovascular disease, thus representing a public health concern. Aerobic capacity is poor in most elders with symptomatic knee OA, and worse than others of the same age.

Weakness in muscles that bridge osteoarthritic joints is multifactorial in etiology. First, there is a decline in strength with age. Second, with limited mobility comes the muscle atrophy of disuse. Third, patients with painful knee or hip OA alter their gait to lessen loading across the affected joint, which further diminishes muscle use. Fourth, "arthrogenous inhibition" may occur, whereby contraction of muscles bridging the joint is inhibited by a nerve afferent feedback loop emanating in a swollen and stretched joint capsule; this prevents maximal attainment of voluntary maximal strength.[6] Because adequate muscle strength and conditioning are critical to joint protection, weakness in a muscle that bridges a diseased joint makes the joint more susceptible to further damage and pain. The degree of weakness correlates strongly with the severity of joint pain and the degree of physical limitation. One of the cardinal elements of the treatment of OA is to improve the functioning of muscles that surround the joint.

For knee and hip OA, trials have shown consistently that exercise lessens pain and improves physical function.[7] Most effective exercise regimens consist of aerobic and/or resistance training, the latter of which focuses on strengthening muscles across the joint. Exercises are likely to be effective, especially if they train muscles for the activities a person performs daily. Activities that increase pain in the joint should be avoided, and the exercise regimen needs to be individualized to optimize effectiveness. Range-of-motion exercises, which do not strengthen muscles and isometric exercises that strengthen muscles, but not through range of motion, are unlikely to be effective by themselves. Low-impact exercises, including water aerobics and water resistance training, are often better tolerated by patients than exercises involving impact loading, such as running or treadmill exercises. A meta-analysis of exercise trials has suggested that, although aerobic, resistance, and performance exercise were all effective for relieving pain in knee OA, single-type exercise programs were substantially more effective than programs including different types of exercise.[8] A patient should be referred to an exercise class or to a therapist who can create an individualized regimen, and then an individualized home-based regimen can be crafted. In addition to conventional exercise regimens, tai chi may be effective for knee OA. Despite the clear-cut effectiveness of exercise for knee and hip OA, there is no strong evidence that patients with hand OA benefit from therapeutic exercise.

In addition, although exercise reduces pain in knee and hip OA patients, physical therapy referral may have little efficacy in relieving pain, at least in hip OA.[9] The reason for the disappointing effect of physical therapy is unclear. Physical therapists may use a combination of treatment modalities for each patient, only some of which are effective, and also patients may not continue to carry out the prescribed exercises after their treatment sessions end.

Adherence over the long term is the major challenge to an exercise prescription. In exercise trials involving patients with knee OA, one-third to more than one-half of patients stop exercising by 6 months, and less than 50% continue regular exercise at 1 year. The strongest predictor of a patient's continued exercise is a previous personal history of successful exercise. Physicians should reinforce the exercise prescription at each clinic visit, help the patient recognize barriers to ongoing exercise, and identify convenient times for exercise to be done routinely (see Table 100-1 for strategies to improve adherence to exercise). The combination of exercise with calorie restriction and weight loss is especially effective in lessening pain.

## Strategies to Realign the Joint

For knee OA especially, misalignment across the joint increases focal load and, when the joint is loaded, such as with walking or other weight bearing, this excess load can translate into pain. Most commonly, knee OA shows varus deformities in which the medial joint is much narrower than the lateral. In normal nondiseased knees, the medial

**TABLE 100-1** Strategies to Facilitate Long-Term Adherence to Exercise and Physical Activity in People with Osteoarthritis

| |
|---|
| Educate patients about the disease and the benefits of exercise. |
| Develop the exercise or physical activity plan with the patient and vary activities to maintain interest and enthusiasm. |
| Use a graded progressive exercise or physical activity program, and ensure that pain and discomfort are not excessive during or after exercise. |
| Initiate exercise under expert instruction, and supervise exercise sessions if possible. |
| Supplement face-to-face instruction with other materials, such as written handouts, videos or DVDs, and online demonstrations. |
| Increase patient self-efficacy by incorporating behavioral techniques such as goal setting, positive reinforcement, use of an exercise contract, and self-monitoring by use of a diary or pedometer. |
| Include the patient's partners and family in the exercise program and garner support from family and friends. |
| Monitor the patients during the long term, with periodic reassessment by a health professional. |
| Supplement exercise instruction with an activity monitor (e.g., a wristband that tracks activity) coupled with goal setting. |

**Figure 100-3** A valgus knee brace used to realign the knee.

compartment bears approximately 60% of the load during walking, but when medial knee OA and varus deformities are present, that load increases to 80% to 100% of weight-bearing load. Joint damage occurs increasingly as a consequence of that load; damage to bone occurs, as evidenced by bone marrow lesions in the medial compartment, and synovitis develops with release of shards of cartilage. Both synovitis and bone marrow lesions are sources of pain. Unloading the medial compartment in these patients by reducing the misalignment might alleviate pain and slow disease progression.

The knee is the fulcrum of a large lever arm, extending when walking from the trunk to where the foot meets the floor. When the knee has a varus (bowlegged) malalignment in the frontal or coronal plane, the knees are farther apart than the feet, and the disease in the knee is more often present in the medial than lateral compartment. A small percentage of patients (approximately 10% to 20%) with knee OA have the opposite—a valgus deformity in which the knees are close together and the feet farther apart. Generally, they have disease in the lateral compartment, which is narrower than the medial compartment. When the knee is malaligned, excessive load during weight bearing is transmitted across the narrowed compartment, often causing damage in that area. Realigning the joint and lessening that malalignment might provide therapeutic benefit. One could focus on changing the position of the foot below the knee at the bottom end of the lever arm or on the position of the trunk, above the knee at the top end of the lever arm. Examples of the former strategy include the use of various shoe orthotics, especially lateral wedge insoles, which can be used to treat medial disease. Lateral wedge insoles that are thicker on the outside than on the inside are placed into the shoe. During walking, these wedges move the knee closer to a vertical line through the center of the body, and in doing so lower the varus moment across the knee, a measure of medial load. However, despite their effect on reducing medial load during walking, trials of wedge inserts have shown[10] that they do not alleviate knee pain compared with neutral inserts, which have no effect on medial loading of the knee. The failure of this promising unloading treatment raises questions about whether unloading of the varus malaligned knee will be effective at all. Reasons for the failure of wedge inserts include the fact that they do not reduce the varus knee moment in all treated patients, the fact that their effect on medial load is small and may be insufficient to produce pain relief, and the fact that patients may not consistently place them in their shoes.

Another strategy that rectifies malalignment and unloads the knee is the use of bracing. With metal struts on the side and straps that force the knee into a more neutral alignment, valgus braces can straighten a knee that has varus malalignment (Figure 100-3). Three randomized trials of valgus bracing in patients with knee OA have been carried out, and two of these have reported that, compared either with neutral braces or with sleeves, the braces had moderate efficacy in alleviating knee pain.[11,12] Unfortunately, adherence to the use of these large bulky braces is poor, and most patients are unwilling to wear them for long periods of time. Thus, even though they are effective, valgus braces have not been a terribly popular treatment for OA. Given their availability and effectiveness, patients with obviously malaligned varus or valgus knees should be presented with the option of obtaining a knee brace. They should be shown pictures of braces so that they can anticipate what wearing them will be like. For a minority of patients, this may be an acceptable effective long-term treatment.

The patellofemoral compartment of the knee is frequently diseased in patients with OA and is a major source

of pain. Because the disease in the patella often affects one compartment preferentially, there is often malalignment of the patella in the trochlear groove; a patellar brace may push the malaligned patella back into the trochlear groove in the femur, increasing the contact area and decreasing the focal load on the diseased patellar compartment. A recent trial[6] suggests that patellar bracing may alleviate knee pain at least over the short term in patients with patellofemoral OA. Patellar braces are easier to wear than the larger bulkier tibiofemoral valgus braces and often fit easily underneath trousers. A less obtrusive option that may have similar mechanism of action is patellar taping, which has been shown[13,14] to relieve knee pain.

Another way to realign the knee is to change the position of the trunk, the top of the lever arm, during walking. In this case, the patient needs to be taught how to position his or her trunk during ambulation so as to lessen malalignment across the knee, a strategy known as "gait retraining." Although promising, this approach has not been comprehensively evaluated, and long-term patient adherence to gait retraining strategies is unclear.

## PHARMACOLOGIC TREATMENTS

### Acetaminophen (Paracetamol)

Many guidelines recommend acetaminophen either on an as-needed or continuous basis as the initial analgesic treatment for OA. Doses as high as 1 g three times daily can be used. Unfortunately acetaminophen, even in high doses, is rarely effective by itself in the treatment of OA. Meta-analyses suggest an effect size of acetaminophen versus placebo of only 0.2 standard deviations, a very small treatment effect.[15] In addition, acetaminophen is a weak cyclooxygenase (COX) inhibitor, with a greater COX-2 than COX-1 effect. There is strong evidence that the use of acetaminophen regularly causes gastrointestinal blood loss and that its overall side effect profile is therefore not necessarily benign.[16] Although its occasional use for treatment of mild OA with occasional pain is recommended, its lack of substantial efficacy suggests that it should not be a primary treatment for moderate to severe OA.[17]

### NSAIDs Including Oral and Topical Agents and COX-2 Inhibitors

NSAIDs are among the most popular treatment for OA. They have both analgesic and anti-inflammatory effects. Meta-analyses suggest that when regularly taken, oral NSAIDs are more effective than high-dose acetaminophen (effect size difference between NSAID and acetaminophen for pain is approximately 0.30, a modest but significant difference).[17] Occasionally, patients treated with NSAIDs experience dramatic and complete relief of pain, but this is not universal. NSAIDs, especially when taken orally, have many adverse effects (see Chapter 59). To lessen the risk of side effects, treatment should be started initially on an as-needed basis or by using topical agents, especially for superficial joints such as the hands and knees. If topical or occasional oral medication is insufficient to control symptoms, then daily regular treatment may be indicated.

NSAIDs cause upper gastrointestinal adverse effects in 30% to 40% of patients, including stomach discomfort, dyspepsia, nausea, and vomiting, and can cause upper gastrointestinal bleeding. These symptoms are partly the result of prostaglandin inhibition in the upper gastrointestinal tract. Prostaglandins are necessary for mucosal protection of the stomach, and inhibiting them makes the stomach mucosa vulnerable. In addition, inhibition of prostaglandins may compromise the perfusion of the superficial lining of the upper gastrointestinal tract, making it more susceptible to injury. Among the risk factors for NSAID-induced gastrointestinal symptoms and complications are higher doses of nonsteroidal drugs; also, particular nonsteroidals increase the risk of gastrointestinal symptoms and bleeding. Based on meta-analyses and a large number of observational studies,[18,19] the most dangerous NSAIDs from the perspective of upper gastrointestinal toxicity are indomethacin, ketorolac, piroxicam, and ketoprofen. The safest nonsteroidals from this perspective are nonacetylated salicylates and nabumetone. The former group of drugs, which are inexpensive and underutilized, do not inhibit gastric prostaglandins and therefore have fewer gastrointestinal side effects than conventional NSAIDs. Nabumetone is a prodrug and has no local prostaglandin-inhibiting effect when administered.

In addition to drug-related factors, there are other known risk factors for NSAID-associated gastrointestinal complications (Table 100-2). Those who need oral nonsteroidals yet who are at high risk should take gastroprotective drugs to lessen their risk. Drugs that protect against gastric and duodenal ulcers based on endoscopic studies include misoprostol, a prostaglandin analog, and proton pump inhibitors. Histamine 2 blockers are not as effective in preventing gastroduodenal complications as are these other two classes of drugs.

In addition to upper gastrointestinal side effects, oral NSAIDs also increase the risk of lower gastrointestinal tract bleeding and perforations. Lower gastrointestinal tract symptoms include diarrhea or constipation, and malabsorption or gut inflammation sometimes accompanies the diarrhea.[20] The rate of mortality from lower gastrointestinal bleeding caused by nonsteroidals may approach that of upper gastrointestinal bleeding related mortality.[21]

COX-2 inhibitors were developed in part to minimize the gastrointestinal side effects of nonsteroidals, but they work by inhibiting prostacyclin which, when inhibited, enhances platelet activation. In addition, COX-2 inhibition causes vasoconstriction. The net effect of COX-2 inhibition is to increase the risk of thrombosis, especially

**TABLE 100-2** Risk Factors for the Development of NSAID-Associated Gastroduodenal Ulcers

| | |

myocardial infarction. When studies confirmed that rofecoxib increased this risk, it was removed from the market, but some NSAIDs still on the market have preferential COX-2 inhibiting effects. Large-scale observational studies and clinical trials have suggested that oral diclofenac,[22] for example, confers a substantial increased risk of myocardial infarction. Other widely used nonsteroidals such as ibuprofen modestly increase myocardial infarction risk (relative risk, ~1.2). The main exception among NSAIDs is naproxen, which does not confer an increased risk of thrombotic events. The risk of celecoxib, the most prominent remaining COX-2 inhibitor on the market, is increased only if high doses of the drug are taken, such as 400 mg per day.

In addition to effects on thrombosis, NSAIDs can also induce congestive heart failure in predisposed patients because they cause retention of fluids and they can increase blood pressure because of renal effects, although the effect on blood pressure is usually small, on the order of an increase of 1 to 2 mm Hg.

Sodium retention is common among patients taking NSAIDs and, when pronounced, can even lead to rises in serum creatinine. Other renal complications of NSAIDs are uncommon, including frank renal insufficiency, papillary necrosis, and interstitial nephritis. Oral nonsteroidals should not be used in patients with stage 4 or 5 renal disease, and should be used cautiously in those with stage 3 disease.

NSAIDs can cause confusion or dizziness, especially in elderly users. In addition, a syndrome known as "anaphylaxis" occurs among some NSAID users. This is a phenomenon mediated not by immunoglobulin (Ig)E but, rather, is a result of prostaglandin inhibition. It occurs especially in aspirin-sensitive patients who often have the syndrome of asthma and nasal or sinus polyposis. Patients in whom anaphylaxis to NSAIDs develops are sensitive to all drugs in the class, except for nonacetylated salicylates, which cause minimal cyclooxygenase inhibition.

When placed into a topical solution with a chemical moiety that enhances penetration of the skin barrier, nonsteroidals can be administered topically. Plasma concentrations of topical NSAIDs are far lower than the same amount of drug administered orally. However, if the drug is administered topically over a superficial joint such as the knees or hands, it can be detected at low concentrations in joint tissues. Randomized trials examining the efficacy of topical nonsteroidals suggest that they are more efficacious than placebo and slightly less efficacious than oral agents.[23] They are much safer than oral nonsteroidals, however, and the only major side effect associated with topical nonsteroidals is redness, burning, or itching on the skin where the medication is applied. This side effect occurs in a large percentage of patients. Strategies for the use of nonsteroidals in OA patients could include an initial trial of topical NSAIDs if the patient has painful knee or hand OA. Another option would be a trial of low-dose, oral, intermittent NSAIDs in patients who are not at high risk for the side effects. If tolerated, the drug dose can be increased.

## Corticosteroids as a Treatment for Osteoarthritis

Because synovial inflammation plays a major role in pain in OA, potent anti-inflammatories such as corticosteroids can be effective in relieving that pain. In fact, intra-articular corticosteroids decrease synovitis,[24] and may work in part by diminishing angiogenesis within the synovium, which secondarily decreases synovial inflammation. In randomized trials testing intra-articular steroids versus placebo injections in knee OA, steroids are more effective than placebo in relieving pain for 1 or 2 weeks. However, the longer-term trial data in knee OA is limited, and for some patients the effects may last much longer. In hip OA, intra-articular steroids have are more effective than placebo for at least 8 weeks.[25,26]

Evidence suggests that withdrawal of synovial fluid may enhance the efficacy of the steroid injection, and that higher doses of steroid tend to have longer-acting effects.

The effect size of intra-articular steroids as a treatment for OA in both knee and hip is large, and intra-articular corticosteroids are probably the most efficacious nonsurgical treatment, at least for pain reduction. They are especially efficacious for treating flares of disease and for cases in which disease is caused in part by the presence of intra-articular crystals, such as calcium pyrophosphate dihydrate crystals. No evidence exists that repeated corticosteroid injections into the joint are dangerous, although some case reports show that high doses of intra-articular corticosteroids may increase the risk of avascular necrosis in the treated joint.

The use of systemic steroids to treat OA, either orally or as intramuscular therapy, is unproven and is currently not recommended, although studies examining the benefits of local and systemic steroids in OA are in progress.

## Opioids

Because joint pain is the predominant symptom in OA, analgesic medications such as opioids could play a role in treatment. Opioids generally act in the central and peripheral nervous system by binding to opioid receptors. They have many side effects, including sedation, constipation, psychological effects, and dependence, which consists of unpleasant withdrawal symptoms if opioid use is discontinued. Meta-analyses[27] have suggested that opioids and tramadol, an opioid-like drug, both have efficacy in treating the pain of OA, but that compared with placebo, that the efficacy is modest at best (effect size vs. placebo of approximately 0.2 to 0.3). For example, a meta-analysis of tramadol has suggested that compared with placebo, its efficacy is somewhat less than the efficacy of oral nonsteroidals for OA. On the other hand, these same meta-analyses suggested that the adverse effect profiles of opioids in OA patients are formidable and that side effects, including major ones, are far more common among patients who take prescribed opioids than among those given placebo in trials. Because of this poor benefit to risk ratio, it is recommended that opioid use in OA be limited. Although concerns have been raised about tolerance to opioids as part of their use in other diseases, there is no evidence that the efficacy of opioids wanes with long-term use.

## Duloxetine

Selective serotonin and norepinephrine reuptake inhibitors (SNRIs) relieve pain in patients with chronic pain syndromes, including fibromyalgia. Duloxetine, an SNRI, is

approved to treat fibromyalgia, chronic musculoskeletal pain, and OA. In trials in patients with OA in which an escalating dose of as high as 120 mg a day was used, duloxetine was superior to placebo in pain reduction, with differences emerging at 2 weeks of treatment.[28,29] However, discontinuation because of side effects was considerably more common among the duloxetine-treated patients. Although these trials may demonstrate the efficacy of duloxetine (and suggest that other SNRIs may also be efficacious for the treatment of pain in OA), chronic widespread pain commonly accompanies painful knee OA. Further, nervous system adaptations occur as part of the chronic pain of OA, leading to allodynia and central sensitization. It may therefore be possible to identify patients who are more likely to respond to duloxetine, people with pain sensitization or chronic widespread pain. This has not been well studied, however.

## CONTROVERSIAL THERAPIES

### Glucosamine and Chondroitin

The signature pathology of OA is loss of hyaline articular cartilage. Both glucosamine and chondroitin are glycosaminoglycans constituents of a large macromolecule in cartilage known as *aggrecan*. These glycosaminoglycans have high negative charges, and during cartilage compression, the negatively charged molecules are forced into close proximity, increasing the electrostatic repulsion force among them. With the end of compression from weight bearing, the electrostatic force predominates and they move away from each other, allowing cartilage to reassume its usual thickness. Thus the chondroitin and glucosamine contribute to the compressive stiffness of cartilage. It is appealing to imagine that one can ingest a molecule that would then be incorporated into cartilage to improve its function. However, glycosaminoglycans are not synthesized from intact chondroitin or glucosamine molecules, and it is unlikely that ingested glucosamine or chondroitin would be incorporated intact into cartilage. While ingested as glucosamine salts (HCl, sulfate), glucosamine at least dissociates completely to glucosamine and its salt in the stomach. Thus the anion accompanying glucosamine is not relevant to the therapeutic effect of glucosamine.[30] Animal studies of glucosamine and chondroitin suggest that they may have anti-inflammatory effects.[30] Other postulated effects include an incorporation of the compounds into cartilage, effects on bone, and indirect effects on the joint via its direct effects on the liver.

Controversy exists regarding the interpretation of clinical trials testing the efficacy of glucosamine and chondroitin in humans. Although large, well-done studies have been performed that support the efficacy of each of these compounds, all nonindustry funded studies have been negative, including one large National Institute of Health (NIH)-funded multicenter study.[31,32] Other publicly funded studies from the United States, Europe, and Canada have all had null findings. One large meta-analysis has suggested that for each of glucosamine and chondroitin, the 95% confidence interval bound around their estimate of efficacy, although excluding a null effect of 0, is not large enough to signify a clinically important effect.[33] All positive trials of glucosamine have emanated from one company that produces a glucosamine sulfate compound, as opposed to the usual preparation sold in the United States: glucosamine HCl. As noted in preceding text, the glucosamine salt dissolves in the stomach so that both HCl and sulfate preparation ultimately produce the same molecule, glucosamine. Based on the results of publicly funded studies and meta-analyses summarizing all trial data on the efficacy of glucosamine and chondroitin major organizations such as the Osteoarthritis Research Society International and the American College of Rheumatology have removed glucosamine and chondroitin from lists of recommended OA treatment.[34,35] Some glucosamine and chondroitin trials have also suggested that these nutraceuticals delay joint space loss, but the NIH-funded gait study found no evidence of this.[36]

### Hyaluronic Acid Injections

When joints such as the knee move back and forth, the motion of one cartilage surface across another is almost frictionless. The lubrication provided by synovial fluid is to the result of several different molecules, among them hyaluronic acid (HA). Concentrations of hyaluronic acid in synovial fluid are diminished in individuals with OA, and that may decrease the viscosity of this fluid during disease. HA may also have direct effects on synovial fluid function. To increase synovial fluid viscosity, a number of compounds of hyaluronic acid have been developed, which are injected into the joint for therapeutic benefit. HA has previously been used in veterinary medicine; in that context it is given either intravenously or as an intra-articular injection.

Preparations of HA, when injected into the joint, are cleared usually after only a few hours, perhaps a day. Purified or synthesized HA products with large molecular weights remain a bit longer, with half-lives within the joint ranging from 17 hours to 1.5 days.[37,38] There are two fundamental types of HA molecules. The first is HA itself, which is a long nonsulfated chain of variable length with repeating disaccharide units. The second is a cross-linked hyaluronan chain that can be water insoluble as a gel. In OA, not only the concentration of HA in the synovial fluid but also the size of individual HA molecules diminishes.[39]

Because HA leaves the joint quickly, yet supposedly produces long-lasting clinical effects, other explanations for efficacy have been suggested, including the idea that synovial sites producing HA are stimulated by injections, although the evidence supporting this explanation is meager.[38] HA has also been thought to have anti-inflammatory and anti-nociceptive effects,[40] but it is difficult to imagine how HA injections would exert prolonged effects, given their transient presence in the joint.

HA injections have been approved by regulatory agencies for the treatment of OA and, depending on the preparation, the course of injections ranges from one to five, usually at weekly intervals. A large number of meta-analyses have assessed the efficacy of HA versus placebo intra-articular injection in trials. It is noteworthy that a large number of unpublished trials have been uncovered, and these have generally shown null results.[41] Among 18 large trials with blinded outcome assessment, the effect size of HA in reducing pain versus placebo was 0.11; statistically significant but clinically irrelevant. HA injections were found to increase

the risk of adverse effects, including flares of pain. Different meta-analyses have concluded that trials of HA either provide no evidence of efficacy or that the evidence suggests minimal efficacy. These meta-analyses have focused on knee OA, for which the preponderance of studies has been carried out. Two randomized trials of hip OA comparing the intra-articular HA injection with articular placebo have shown no efficacy of treatment. The recent Osteoarthritis Research Society International guidelines for OA rated hyaluronic acid as uncertain in its efficacy for knee OA and inappropriate for other types of joint OA. The American College of Rheumatology guidelines for the treatment of OA did not make recommendations regarding the use of hyaluronic acid injections for either knee or hip. The National Institute for Health and Care Excellence (NICE) guidelines recommends against offering intra-articular hyaluronate injections. Based on findings from a meta-analysis of pharmacologic treatments in OA,[42] intra-articular injections (including intra-articular placebo) are more efficacious in general than orally administered drugs, and a favorable patient response to HA may be explained, in part, by its delivery method.

### Tetracyclines

Although tetracyclines inhibit enzymes that break down cartilage, doxycycline, tested in a large trial for OA, was not found to consistently protect joints from progressive OA, or to alleviate pain.[43]

### Hydroxychloroquine

Given the potential influence of articular inflammation of joint pain and joint destruction, it is appealing to assume that a drug that abrogates inflammatory processes would be efficacious not only for rheumatoid arthritis but also for OA, especially hand OA, where inflammation is so clinically evident. However, there is an absence of evidence on the efficacy of hydroxychloroquine for OA, and it is not recommended in treatment guidelines.

## UNPROVEN REMEDIES IN OSTEOARTHRITIS

OA is a painful chronic condition that affects many millions of people throughout the world. Furthermore, approved and effective medical therapies, most of them described in this chapter, are often not very effective in alleviating all the pain and discomfort of disease. That has left a major opening for companies and entrepreneurs to market unproven remedies as effective treatments for OA. From copper bracelets to ginger to health food supplements, a multitude of treatments, many with little scientific rationale, are advertised as effective for OA pain. The market for these unproven remedies is large. Any health food store, many pharmacies, and websites with a focus on arthritis, contain ads and opportunities to purchase many of these supposedly effective treatments. Patients will ask whether there is evidence that they work, and many will be convinced that they or a close friend or relative have been helped by use of one or more of these treatments.

The threshold that distinguishes an unproven treatment from a treatment that fits within the accepted armamentarium is a fine and blurred line. To be a proven therapy, a treatment needs to have a convincing biologic rationale or mechanism of action that can be proven. Also, randomized clinical trials must demonstrate the efficacy of the treatment. Glucosamine constitutes an excellent example of this blurred line as noted above. For many unproven remedies, there is not as much evidence as there is for glucosamine. In some cases, there is one industry-sponsored trial that reports efficacy, perhaps from a developing country, where trials are often reported as positive. There may be a history of use of this treatment for OA or cultural support among particular communities for its use. There may be some suggestive evidence that a health food or vitamin contains a compound that might be therapeutic, and an industry-sponsored trial that purportedly demonstrates efficacy. Such is the case for ginger, which has some mild anti-inflammatory effects.

For many unproven remedies, the biologic rationale or mechanism of action is unclear, and there may not be a placebo-controlled randomized trial that suggests efficacy. Because the market is so large and potentially lucrative for those marketing potential treatments for OA, it is not surprising that manufacturers and producers will present rationales for treatment that may not be credible, and that randomized trials are carried out the results of which may not be trustworthy.

In evaluating whether patients should be given unproven remedies, several different considerations emerge. First, placebo treatments in OA[44] often work moderately well to relieve pain, and their effect on pain compared with no treatment at all is sometimes greater than that of effective treatments compared with placebo. Intra-articular injections are especially likely to be effective.[42] Some authors have recommended that if the unproven remedy is benign, then clinicians should provide it to patients even if it is no better than placebo. Given these considerations, when faced with a patient who insists that a specific unproven remedy has been of value for them or those close to them, the clinician should strongly consider not disabusing patients of this notion and should try to take advantage of whatever effect this treatment has, whether it is real or placebo based.

## SURGERY FOR OSTEOARTHRITIS

### Arthroscopy and Meniscal Surgery

Many knees affected by OA also have coexistent meniscal tears. These knees often are painful and sometimes have mechanical symptoms, such as catching or locking, which may be referable to their tears. Several randomized trials comparing surgery to no surgery have shown consistently that arthroscopy with meniscal surgery is not effective for these patients. In addition arthroscopy with lavage and débridement is no more effective than no surgery at all.[45,46] Even mechanical symptoms presumably related to the meniscal tears often do not respond to arthroscopic surgery.

Short of knee replacement, what surgical options are available for patients with OA? If knees have isolated compartment involvement, such as medial tibiofemoral disease, orthopedists may choose to do osteotomies, which break the

tibia and can realign the knee to correct malalignment. Alternatively, they can carry out unicondylar replacement with realignment. Both of these surgeries may delay the knee for a knee replacement or even obviate it. Of the two approaches, osteotomies are becoming less popular as there are fewer surgeons familiar with carrying them out.

## Total Joint Arthroplasty

Knee and hip replacements are efficacious and cost-effective for patients with advanced osteoarthritis who have severe pain. There is little agreement among surgeons, practitioners, or even patients as to exactly which patients ought to get knee or hip replacement.[47] Indications not only vary among surgeons, but they also vary across countries. However, a number of investigators in different countries have suggested that particular patients are good candidates for knee or hip replacements. Recommended indications are shown in Table 100-3 based on a recent survey of patients and orthopedists. Although these guidelines focus on pain and disability, surgery should be reserved for those whose symptoms have not responded to nonsurgical treatments, such as exercise and anti-inflammatory drugs. The major determinant of the need for surgery is pain, and not necessarily radiographic severity or the amount of joint destruction. Many patients with severe joint destruction have surprisingly little pain; whereas others whose radiographs do not show advanced disease are disabled by pain. Among these two contrasting groups, those with disabling pain are likely to be better candidates for knee replacement, although recent data[48] suggest that those in whom a knee replacement is most likely to fail are often those whose radiographic disease at the time of surgery is extremely mild. This may be because the knee pain experienced by these patients is not actually the result of knee OA but, rather, more diffuse pain syndromes such as fibromyalgia.

The indications for knee and hip arthroplasty are not necessarily the same. Hip arthroplasty is, on average, a more successful operation, with faster rehabilitation times than knee replacement. That suggests that the threshold for seeking a hip replacement might be lower than that for knee replacement. For patients undergoing knee replacements, 20% to 30% have persistent pain and disability, even 2 or more years after the operation, and the rehabilitation after knee replacement often takes several months, in part to regain full range of motion. Risk factors for a poor outcome after knee replacement include the presence of pain in the contralateral knee or other joints,[49] and the presence of a higher comorbidity burden. Although those with worse pain and disability have greater absolute improvements in their pain and function scores after joint replacement, they still are left with more functional limitations than those who went into joint replacement with milder functional limitations.

Although obese individuals also experience the benefits of knee and hip replacement, the failure rates of these prostheses is higher. Younger patients (those younger than 60 years) are increasingly presenting with a need for knee and hip replacement. In the United States, especially, there is a marked increase in the rates of knee and hip replacement among these people, and although prostheses last many years, it is unclear whether the durability of prostheses will be the same in patients who undergo the surgery at a younger age, in large part because they are far more active than older patients. Patients who meet clinical criteria for knee or hip replacement and are age 60 years and older are old enough to benefit from the surgery without being at high risk of loosening or other joint failure. Increasingly it is thought that patients 55 years and older have a similar benefit to risk ratio, but it is unclear whether those younger than 55 years will similarly benefit without an increased risk.

Although patients with OA that affects the thumb base (the first carpometacarpal [CMC] joint) often experience a reduction in pain and improvement in hand function after surgery, the surgical approaches are varied, and it is unclear which has better outcomes.[50] Options include trapeziectomy and the same surgery with tendon interposition and/or ligament reconstruction, CMC fusion, and even total joint replacement.

Other joints affected by OA may benefit from joint replacement. Although glenohumeral joint OA is uncommon, evidence[51] suggests that patients with this disorder who undergo shoulder joint arthroplasty experience a marked reduction in pain. Ankle joint OA, usually a consequence of trauma to the ankle, can be treated with either ankle joint replacement or ankle fusion.

**Table 100-3** Indications that Patients May Be Good Candidates for Hip or Knee Replacement

| |
|---|
| Patients report that arthritis symptoms are negatively impacting their overall quality of life. |
| The patient has evidence of arthritis on examination (clinical and radiographic/imaging) of the joint being considered for surgery. |
| The patient has had an adequate trial of nonsurgical arthritis treatment. |
| The patient's expectations for joint replacement surgery are achievable. |
| The patient is physically and mentally ready to have surgery. |
| The patient and surgeon agree that the potential benefits to the patient of joint replacement surgery outweigh the potential surgical risks. |

## Joint Distraction

A novel and still experimental approach to treating OA is joint distraction arthroplasty, in which an external fixation frame bridging the joint is fixed with two bone pins on each side of the joint, and the frame gradually elongates, increasingly distracting the joint and separating one side of the joint from the other. The tubes with distraction are applied for approximately 2 months, after which they are removed. One effect of this distraction is to unload the osteoarthritic joint. This approach has been used most often for ankle OA, for which surgical and other treatments are limited. The joint space or bone-to-bone distance in the ankle increases in many patients after distraction arthroplasty, especially of the ankles, and more comprehensive studies have suggested that cartilage redevelops within the joint, although it is

not clear whether this is hyaline articular cartilage. Bone marrow lesions also appear to shrink or even resolve. Recent reports suggest that distraction arthroplasty might additionally be successful for knee OA,[52] at least at a follow-up of 24 months. Although promised as a treatment, distraction arthroplasty requires the patient to wear the fixation device around the affected joint for a couple of months with limited activity during that time, and the long-term effects beyond 2 years are not well documented.

CHAPTER 101

# Metabolic Bone Disease

Nancy E. Lane

**KEY POINTS**

- Osteoporosis is a disease defined by low bone density and deterioration of microarchitecture, which reduces bone strength and increases fracture risk.
- Major clinical risk factors for osteoporotic fractures include older age, low weight, family history of hip fracture, fracture occurring after age 50 years, glucocorticoid use, and inability to rise from a chair without assistance. More than 50% of osteoporosis in men results from secondary causes.
- Post-menopausal and age-related bone loss results from an uncoupling of bone remodeling such that bone resorption is greater than bone formation, resulting in a net loss of bone.
- Evaluation for risk of osteoporotic fractures with the Fracture Assessment Index (FRAX) for post-menopausal women and for men is critical to determine which persons have a 10-year fracture risk (for the hip and major osteoporotic fracture sites) that is high enough to warrant treatment.
- Treatment of high-turnover osteoporosis resulting from estrogen deficiency with anti-resorptive agents (e.g., estrogen, raloxifene, and bisphosphonates [alendronate, risedronate, zoledronic acid, ibandronate, and denosumab]) and an anabolic agent (recombinant human parathyroid hormone 1-34) can reduce incident vertebral fractures.
- Treatment for osteoporosis with bisphosphonates should continue for 3 to 5 years, after which, if the bone mineral density T-score is greater than –2, the subject has not sustained a fracture, and the overall risk of fracture is low, the treatment can be discontinued and the patient can be observed.
- Parathyroid hormone (PTH) increases osteoblast maturation and life span, increases trabecular bone mass and cortical thickness, improves bone strength, and decreases fractures. Anti-resorptive therapy is necessary after a full course of PTH to maintain newly formed bone mass.
- Glucocorticoid-induced bone loss results from increased osteoclast activity and reduced osteoblast activity and is most severe in the first 6 months of therapy. Bisphosphonate treatment can prevent fractures, and treatment with hPTH (1-34) can reverse glucocorticoid-induced osteoporosis and reduce incident fractures.
- Aromatase inhibitors reduce levels of serum estrogen and result in rapid bone loss in post-menopausal women undergoing adjuvant breast cancer therapy.
- Gonadotropin-releasing hormone agonists decrease testosterone and estrogen levels and cause bone loss in men being treated for prostate cancer.

Osteoporosis is characterized by low bone density and a deterioration of bone microarchitecture that reduces bone strength and increases the risk of fracture. The hallmark of osteoporosis is the loss of both bone mineral and bone matrix. Bone consists of an organic matrix (collagen and noncollagenous proteins) and an inorganic mineral component (calcium and phosphate in hydroxyapatite crystals; see Chapter 4). Normally, bone turnover is tightly coupled with osteoclast-mediated bone resorption followed by osteoblast-stimulated bone formation. This delicate balance in bone remodeling results in no net change in skeletal mass. Osteoblasts synthesize osteoid–bone matrix that subsequently undergoes mineralization and becomes mature bone matrix. The skeleton contains approximately 80% cortical bone, which is concentrated in the appendicular skeleton and femoral neck, and 20% more metabolically active trabecular bone, which is located in the spine, epiphyses, and pelvis. Osteoporosis is characterized by reduced bone strength that is usually accompanied by a reduction in bone mass. Osteomalacia encompasses disorders in which there is decreased mineralization of bone matrix. Paget's disease is a skeletal disorder characterized by increased rates of bone turnover with the development of disorganized woven bone.

## OSTEOPOROSIS

### Epidemiology and Clinical Signs

Osteoporosis, the most common metabolic bone disease, affects 200 million persons worldwide. Approximately 28 million Americans have osteoporosis or are at risk for it. *Osteoporosis*, or "porous bone," is a "disease characterized by low bone mass and structural deterioration of bone tissue, leading to bone fragility and an increased susceptibility to fractures, especially of the hip, spine and wrist."[1] Although usually asymptomatic, osteoporosis can produce loss of height, pain, dowager's hump, and increased risk of fracture. After 50 years of age, an exponential rise in fractures occurs, with 40% of women and 13% of men experiencing one or more osteoporotic fractures in their lifetimes. In the United States alone, more than 1.5 million osteoporotic fractures occur annually, including 250,000 hip, 250,000 wrist, and 500,000 vertebral fractures. Hip fractures are associated with a 12% to 24% mortality rate in women and a nearly 25% mortality rate in men within the first year of fracture; in addition, 50% of patients are unable to ambulate independently and require long-term nursing home care.[2] These numbers will continue to grow exponentially as the elderly population of industrialized nations increases.

Bone accretion occurs during adolescence, when there is a large increment in bone mass. Peak bone density is normally achieved after puberty and into the third decade of life. However, by age 22 years, most persons have achieved nearly all of their peak bone mass. At menopause, an acceleration of bone loss usually occurs over approximately 5 to 8 years, with an annual 2% to 3% loss of trabecular bone and a 1% to 2% loss of cortical bone. Both men and women lose bone with age. Over a lifetime, women lose approximately 50% of trabecular and 30% of cortical bone; men generally lose two-thirds of these amounts.[3] Osteoporosis was previously thought to be a silent disease that was part of the normal aging process. However, the advent of bone densitometry has made it possible to accurately and reproducibly identify patients at risk for osteoporosis so that prevention and treatment strategies can be instituted to reduce the incidence of fractures. With a health care expenditure of $13.8 billion annually for osteoporosis-related fractures and a projected threefold rise in these costs during the next 40 years in the United States, the institution of effective prevention and treatment strategies to reduce fractures is of great importance.[1,4]

## Pathophysiology of Menopausal and Age-Related Bone Loss

Bone is constantly undergoing remodeling, whereby areas of bone resorption produced by osteoclastic action are replaced by bone laid down by osteoblasts. Osteoporosis results from an imbalance between bone resorption and formation. The initiation of bone remodeling is still being debated; however, the osteocytes, or terminally differentiated osteoblasts, located within the bone matrix and connected to one another and the bone surface may release chemical mediators that attract osteoclasts to the bone surface (Figure 101-1). Osteoclasts originate from hematopoietic stem cells that differentiate into colony-forming unit granulocyte-monocytes that differentiate into osteoclasts, are attracted to the bone surface, attach to the bone matrix, and resorb bone tissue. Generally, bone resorption is rapid, and a resorption pit is formed within 10 to 14 days. After bone resorption is complete, osteoblasts, which are derived from the bone marrow mesenchymal stromal cells, attach to the resorbed bone surface and produce osteoid, which is then mineralized. Bone formation can take up to 3 or 4 months, and thus a normal bone remodeling cycle in adults can last 4 to 6 months (see Figure 101-1A). A number of metabolic changes such as estrogen deficiency, immobilization, metabolic acidosis, hyperparathyroidism, and systemic and local inflammatory diseases can increase osteoclast number and activity, uncoupling bone turnover. This process results in greater bone resorption than bone formation and a net loss of bone tissue. New data show that a number of local factors in bone affect the regulation of bone formation and resorption and the coupling of these processes. These factors include insulin-like growth factors (IGFs), interleukins (IL-1, IL-6, and IL-11), TNF, receptor activator of nuclear factor-κB ligand (RANKL), and TGF-β.[5] Animal studies have shown that IL-1, IL-6, and TNF knockout mice do not lose bone with estrogen deficiency.[6] In addition, inflammatory arthritis animal models show that TNF, IL-1, and IL-6 are all strong stimulators of osteoclastic bone resorption. This link between the immune system and the maintenance of bone mass is intriguing, but additional work is required before we can understand its significance.

A number of mechanisms underlie primary osteoporosis, including a low peak bone mass as a young adult and rapid bone loss during menopause. Factors contributing to age-related bone loss include impaired calcium absorption with age, a compensatory rise in parathyroid hormone (PTH) levels, and greater resorption than formation of bone. Estrogen deficiency is associated with the release of cytokines including RANKL, IL-1, IL-6, and TNF, which leads to the recruitment and stimulation of osteoclasts in the marrow and increased production of bone-resorptive cytokines, which may contribute to menopause-related bone loss.[5] Estrogen therapy inhibits IL-1 release, and in oophorectomized rats and mice, an inhibitor of IL-1 (the IL-1 receptor antagonist) suppresses bone loss.[6] IL-6 levels also increase with age in human marrow cultures[7] and in peripheral monocytes. IL-1 and TNF induce the production of IL-6 from osteoblasts and stromal cells. Further evidence supporting a role of IL-6 in bone turnover includes data showing that oophorectomized IL-6 knockout transgenic mice do not lose bone.

Two other proteins that influence osteoclast activity have been identified: osteoprotegerin (OPG) and RANKL, which are produced by osteoblasts.[8] Estrogen deficiency increases osteoblast production of RANKL, which stimulates maturation and activity of osteoclasts by attaching to RANKL on the surface of immature and mature osteoclasts. Simultaneously, estrogen deficiency decreases osteoblast production of OPG, the decoy receptor that reduces RANKL production and activity. Adenoviral delivery of OPG ameliorates bone resorption in a mouse ovariectomy model of osteoporosis.[8] Both pre-clinical animal models and clinical trials of women with low bone mass have been completed and demonstrate that inhibition of RANKL with an anti-RANKL monoclonal antibody prevents estrogen-deficiency bone loss.[9]

In addition, a number of genetic, nutritional, and lifestyle risk factors predispose to the development of osteoporosis. Whites and Asians are at risk for low bone mass and osteoporosis, whereas African-Americans have a higher bone density and one-third to one-half the number of fractures.[1,8,9] Some studies show that African-Americans have lower vitamin D and urinary calcium levels, higher PTH levels, and skeletal resistance to the effects of PTH on bone.[10-12] Studies in twins and families show that up to 80% of the variance in bone mass is accounted for by genetic factors.[13] A maternal history of hip fracture, for example, is associated with a twofold increased risk of a hip fracture.[14] Data from Uitterlinden and colleagues[15] show that the gene encoding collagen type IA1 is associated with low bone density with increasing age and an increased risk of fracture. In the *ss* allele group, bone density was 12% lower at the femoral neck and 20% lower at the lumbar spine than that in the *SS* group, indicating an increased gene-dose effect with increasing age. However, *COLIA1* is associated with a lower baseline bone density and not an increased rate of bone loss. Further, genetically determined architectural features of bone such as a long hip axis length may contribute to increased fracture risk; conversely, a short hip axis length

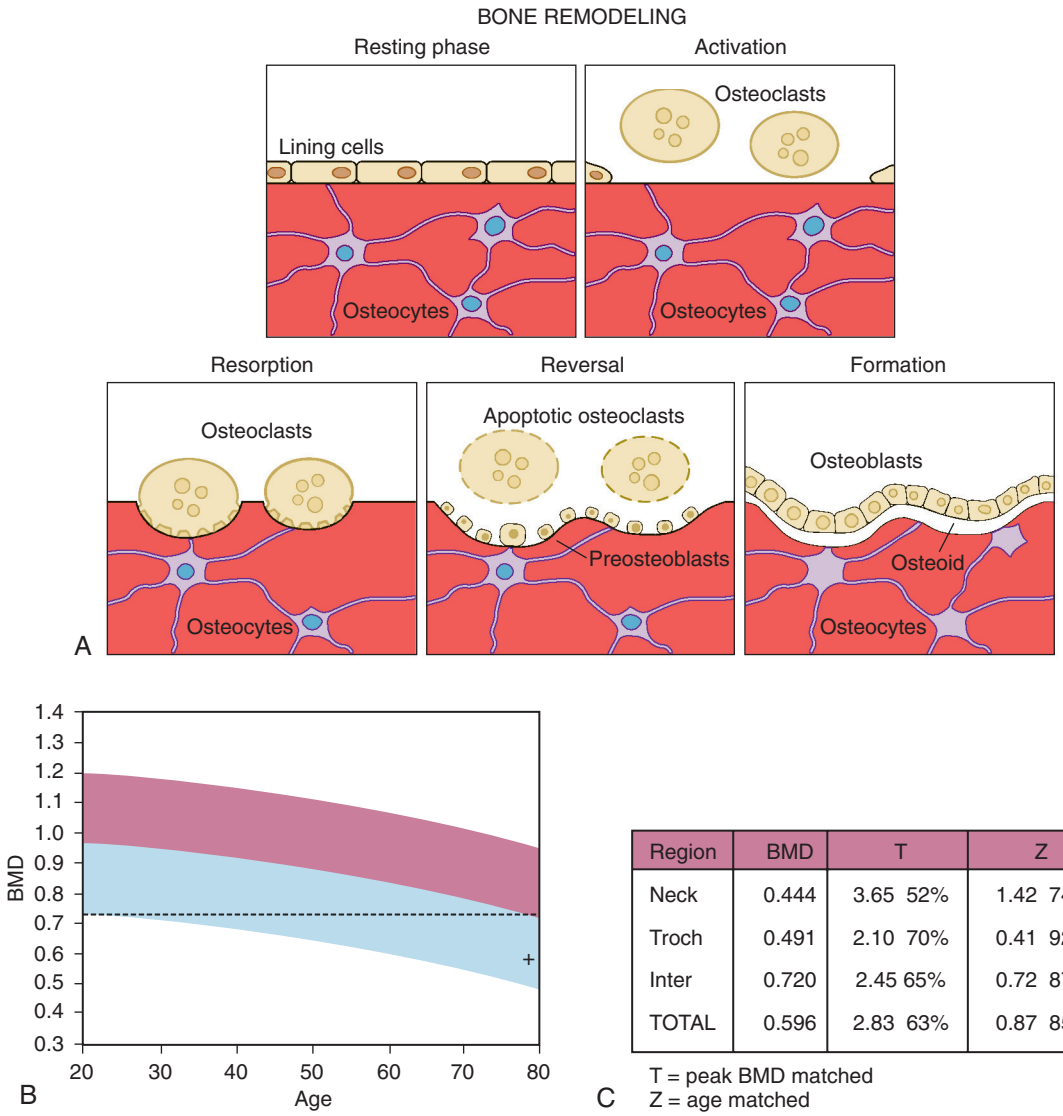

**Figure 101-1** **A,** The bone remodeling cycle. Osteocytes most likely release chemicals to the bone surface that attract osteoclasts. Osteoclasts attach to the bone matrix, create a tight ring, and release acid that lowers the pH and dissolves the mineral from the bone matrix. After the mineral is released, the demineralized matrix is broken down. The osteoclast leaves the bone surface, and an osteoblast is attracted to the area of the bone that was resorbed. The resorption phase is about 10 to 14 days. Osteoblasts produce new bone, or osteoid, that fills in the resorption pit. Also, some of the osteoblasts are left within the bone matrix as osteocytes. The osteoid mineralizes over about 3 months, and the bone remodeling cycle is complete. **B** and **C,** The bone density of a post-menopausal woman is compared with that of both young, normal control subjects and age- and gender-matched control subjects. The + shows this patient's age and bone mineral density (BMD); the blue and purple regions represent the BMD for the patient's age plotted with respect to the manufacturer's reference range (equivalent to a Z-score). The T- and Z-scores represent the number of standard deviations below young, normal control subjects and age-matched control subjects, respectively. Because the bone density provides a gradient of fracture risk, therapies can be instituted to prevent the development of osteoporosis or to treat patients at increased risk for fracture. Inter, Intertrochanteric; Troch, trochanteric.

confers some protective effect.[16] Recently, a family has been described whose members have high bone mass but are otherwise phenotypically normal. This family has a mutation (an amino acid change) in the low-density lipoprotein receptor–related protein 5 (LRP5). Using in situ hybridization to a rat tibia, expression of LRP5 was detected in areas of bone involved in remodeling. Additional studies have reported that this LRP5 mutation increases wnt signaling, which may alter bone mass through a primary defect of bone formation. Persons with this mutation demonstrate normal levels of bone resorption, but specific markers of bone formation are strikingly elevated. The observation that LRP5 is expressed at high levels in osteoblasts is consistent with LRP5 having a role in this area. Further work is now required to determine whether other mutations in the chromosome containing the LRP5 segment are associated with a variation in bone density in the general population.[17,18]

Recently, genome-wide scans have been performed in a number of cohorts and have found a number of single nucleotide polymorphisms (SNPs) that are associated with osteoporosis (fracture or bone mineral density [BMD] associations). They include VDR, ESR1, ESR2, LRP5, LRP4, SOST, GRP177, OPG, RNAK, RNAKL, COL1A, SPP1, ITGAI, SP7, and SOX6, which can be reasonably assigned as confirmed or replicated, and another 30 or so genes that are promising candidates. It is of note that confirmed and

**TABLE 101-1** Risk Factors for Osteoporosis

| |
|---|
| **Primary** |
| Previous fracture after age 30 yr |
| Family history of hip fracture |
| Cigarette smoking |
| Weight <127 lb |
| Low bone mineral density |
| **Secondary** |

Modified from LeBoff MS: Calcium and metabolic bone disease. In *Medical knowledge self-assessment program,* Philadelphia, 1995, American College of Physicians.

promising genes are clustered in three biologic pathways: the estrogen endocrine pathway, the Wnt/beta-catenin signaling pathway, and the RANKL/RANK/OPG pathway. New biologic pathways will certainly emerge when more osteoporosis genes are identified and validated.[19] Other risk factors for osteoporosis, as enumerated in Table 101-1, include low body weight and reduced gonadal steroid levels.[13] According to some reports, lifestyle factors that may contribute to the development of osteoporosis include cigarette smoking, excessive alcohol intake, reduced physical activity, and inadequate calcium intake. Cigarette smokers have poorer health than do nonsmokers, along with impaired calcium absorption, lower estrogen levels, earlier menopause, and more fractures, and they exercise less; smoking cessation reverses this risk of osteoporosis.

In a large, prospective study of 9516 women older than 65 years, the following lifestyle factors significantly increased the risk of hip fracture: no walking for exercise, intake of more than two cups of coffee daily, current use of long-acting benzodiazepines and anticonvulsant drugs, current weight less than weight at age 25 years, height greater than 5 feet 7 inches, age older than 80 years, fracture since age 50 years, inability to stand from a chair without using arms, poor depth perception, and self-evaluation of health as fair to poor.[14] Low bone density in conjunction with a fall or trauma predisposes an individual to a fracture. Poor health and compromise of neuromuscular function increase the risk of osteoporosis and falls, which in turn increase the risk of hip fracture.[14] Importantly, elderly white women with both a low bone mass and more than two risk factors have a nearly 20-fold increased risk for fracture.

Secondary causes of bone loss that can affect women and men of all ages and races are listed in Table 101-2. Glucocorticoid therapy is the most common secondary cause of bone loss. Osteoporotic fractures develop in an estimated 30% to 50% of patients treated with glucocorticoids.[20] Glucocorticoid therapy causes bone loss through a number of different mechanisms such as producing a negative calcium balance through impaired intestinal calcium absorption, increasing urinary calcium excretion, decreasing bone formation, dose dependently increasing apoptosis of osteocytes and osteoblasts, increasing bone resorption by stimulating osteoclast activity by macrophage colony-stimulating factor, and suppressing endogenous gonadal steroid production.[21] Therapy with glucocorticoids leads to an early and, in some instances, dramatic loss of trabecular bone, with less effect on cortical bone. In hyperthyroidism (Graves' disease or toxic nodule) or supraphysiologic therapy with thyroid hormone, the ensuing accelerated bone turnover may produce a reduction in bone mass when the thyroid-stimulating hormone level is suppressed, even when thyroid hormone levels are within the normal range.[22] Athletic amenorrhea, anorexia nervosa, and other hypogonadal states, including the use of gonadotropin-releasing hormone

agonists,[23,24] may result in bone loss. In addition to estrogen deficiency, women with anorexia nervosa have low levels of IGF-I and reduced levels of adrenal androgen dehydroepiandrostenedione, which may contribute to the development of osteoporosis.[25]

### Osteoporosis in Men

Osteoporosis in men was not recognized 20 years ago but is now a major public health problem because of men's recently increased life span. The epidemiology of osteoporosis in men is just now being evaluated. Fracture risk occurs in adolescence and young adulthood and then increases after the age of 70 years. Long bone fractures occur more commonly in young men, whereas hip and spine fractures are more prevalent in men older than 70 years. The increase in fractures in older men is just as significant as it is in women, but it occurs about 10 years later in life, with an age-adjusted incidence of hip fractures in men of about one-third to one-half that of women.[26] Elderly men who sustain hip fractures have a greater risk of dying within the first year or being permanently disabled compared with women.[26] Recent data from the Study of Osteoporotic Fractures in Men (MrOS) determined that, after 15 years of follow-up, men of an older age (>75 years) who had low femoral neck BMD, a history of a previous fracture, divorced marital status, greater height, use of tricyclic anti-depressants, and a history of hyperthyroidism (Graves' disease) were independently related to an increased risk of hip fracture with low femoral neck BMD. In addition, in men with a low BMD (ranging from −1 to −2.5), the risk of hip fracture incidence increased from 4/1000 patient years to 40.2/1000 patient years).[27]

Osteoporosis in men can result from a number of secondary causes; for instance, hypogonadism causes an increase in bone turnover and rapid bone loss as gonadal function declines with age. At this time, severe hypogonadism from androgen deprivation therapy for prostate cancer is common in elderly men. The exact role of estrogen and androgens in male skeletal health is not yet known. Although estrogen is necessary for the young male skeleton, serum estrogen levels are highly correlated with bone remodeling, BMD, and the rate of BMD loss in older men; the associations are stronger than with testosterone. However, serum testosterone levels are also highly correlated with indices of bone resorption and formation. The roles of estrogen and testosterone in the male skeleton require additional investigation.[28] Some of the other common causes of osteoporosis in men that are not as frequent in women are alcoholism, gastrointestinal disorders, including hepatic disorders, and malabsorption.[26]

### Osteoporosis in Rheumatic Diseases and Other Conditions

Recently, studies have reported significant bone loss in patients with systemic inflammatory diseases such as rheumatoid arthritis, systemic lupus erythematosus (SLE), and ankylosing spondylitis. Patients with rheumatoid arthritis experience periarticular and generalized bone loss and an increased incidence of fractures compared with the general population.[29] T lymphocytes, tissue macrophages, and synovial-like fibroblasts release inflammatory cytokines (IL-1, TNF, and IL-6) and inhibitory wnt signaling proteins such as dkk-1 and RANKL, which stimulate preosteoclasts in the bone marrow and synovium to actively resorb bone; in addition, osteoblast maturation is altered.[30,31] In an animal model of inflammatory arthritis induced with collagen, animals pretreated with OPG did not have bone loss within the periarticular bone or the presence of erosions.[32]

Additional factors that might contribute to osteoporosis in patients with rheumatic diseases include decreased mobility, glucocorticoid therapy, and systemic inflammation.[33] Some data, however, show that low-dose glucocorticoid therapy in women with rheumatoid arthritis does not have adverse skeletal effects, possibly because of a decrease in disease activity in association with the suppression of inflammatory cytokines and improved physical activity and function.[34,35] Ankylosing spondylitis is also associated with fractures and reduced bone density in the spine and proximal femur, even early in the disease.[36] Patients with SLE have a high rate of osteoporotic fractures in the presence of low to normal bone mass, suggesting that systemic inflammation alters bone turnover. Increased serum levels of TNF can reduce osteoblast maturation and increase osteoclast maturation and activity; in addition, other inflammatory factors such as oxidized low-density lipoproteins and inflammatory high-density lipoproteins can direct mesenchymal stem cells to differentiate into adipocytes instead of osteoblasts and impair bone mass.[37] Infiltrative processes in the marrow such as multiple myeloma, mastocytosis, and Gaucher's disease may produce osteoporosis. Patients with Gaucher's disease show an accumulation of glucocerebrosides in macrophages in the spleen, liver, and bone marrow, which causes hepatosplenomegaly, anemia, thrombocytopenia, bone infarcts and infections, fractures, and aseptic necrosis.[38]

The immunosuppressant drug cyclophosphamide (Cytoxan) induces amenorrhea and hypogonadism, which may increase the risk of bone loss. Women who undergo premature menopause from cyclophosphamide therapy can have estrogen-deficiency bone loss in their thirties. Young women with SLE who try to preserve ovarian function while undergoing cyclophosphamide therapy by taking gonadotropin-releasing hormone agonists may also experience estrogen-deficiency bone loss. In rodent models, the immunosuppressive drug cyclosporine produces a time- and dose-dependent bone loss[39]; in contrast, azathioprine (Imuran) and rapamycin (sirolimus) do not appear to adversely affect skeletal homeostasis.[40] Therapy with both cyclosporine and prednisone in transplant recipients is associated with early accelerated bone loss after the initiation of treatment and the development of osteoporosis and fractures with continued exposure.[41]

Vitamin D deficiency may also manifest as osteopenia and fractures, but this condition is both preventable and treatable.[42] Vitamin D insufficiency is common in older patients and in persons with SLE who do not get an adequate amount of sunlight or who use potent sunscreens. Also, patients with malabsorption syndromes and liver disease can have vitamin D deficiencies. Unlike the situation in osteoporosis, very low vitamin D levels are often characterized by a mineralization defect and osteomalacia. Vitamin D deficiency is reported to be present in up to 50% of women with hip fractures.[42]

## Assessment of Bone Density and Osteoporotic Risk

Osteoporosis may first be diagnosed when a radiograph shows signs of demineralization or a spinal film shows evidence of compression fractures of vertebral bodies. Because an estimated 25% to 50% of bone mass must be lost to show osteopenia on radiographs, conventional radiography is an insensitive technique for diagnosing bone loss. Radiographs may demonstrate signs of secondary causes of osteoporosis such as the presence of subperiosteal resorption in persons with hyperparathyroidism, characteristic lytic changes or bone infarcts in persons with Gaucher's disease, local sites of lytic destruction in persons with malignancy, and pseudofractures in persons with osteomalacia. Bone densitometry makes it possible to measure the amount of bone in the relevant fracture sites of the spine, forearm, and proximal femur, as well as the total body.

Techniques for evaluating bone mass include dual-energy x-ray absorptiometry (DEXA) and quantitative computed tomography (CT) scanning of the spine.[1,2] Bone density evaluations using DEXA incorporate the attenuation of soft tissue and bone by radiographs to calculate the BMD. DEXA is both precise and safe, with a low degree of radiation exposure. With reproducibility errors of approximately 0.6% to 1.5%, this technique can detect small changes over time.[2,43,44] Further, newer DEXA techniques measure bone density rapidly, in 0.5 to 2.5 minutes. Quantitative CT scanning allows for the direct measurement of trabecular bone in the central region of the spine, but the procedure entails a comparatively high radiation exposure, and time and precision errors are usually higher than those associated with DEXA.

Figure 101-1B and C show the BMD in a postmenopausal patient compared with that of young, healthy control subjects to determine if there is reduction in BMD compared with peak bone mass (i.e., the percentage of young healthy control subjects expressed as a T-score) and with age-matched control subjects to assess whether BMD is diminished relative to an age-matched cohort (the percentage of age-matched control subjects expressed as a Z-score). An inverse relationship exists between bone density and the gradient of risk for fracture.[45] Prospective studies show that bone densitometry identifies patients with an increased gradient of risk for fracture. In 8134 women, a 1 standard deviation (SD) decrement in the bone density of the spine and the femoral neck compared with age-adjusted control subjects was associated with a 1.6- and 2.6-fold increased risk of hip fracture, respectively.[46] Measurement of bone density in the hip is more predictive of hip fracture than is measurement at another site. Studies show that in women older than 65 years, hip bone density is predictive of spine and hip fracture and that conventional spine density does not add to the diagnostic utility of a single hip bone density test in assessing the risk of fracture.

Although bone densitometry provides a quantitative measure of bone mass, in vitro studies using ultrasonography indicate that this technique also provides information about the mechanical properties of bone, including both density and elasticity. These qualities are strong predictors of bone strength. Ultrasound techniques include speed-of-sound and broadband ultrasound attenuation methods; the speed-of-sound technique reflects bone density and elasticity, and broadband ultrasound attenuation is an indicator of bone density, bone structure, and composition. Both ultrasound techniques have been approved for clinical use by the U.S. Food and Drug Administration (FDA) and have been shown to discriminate between normal and osteoporotic patients at increased fracture risk.[47] The T-score parameters used by some ultrasound machines do not correspond to T-score levels as measured by DEXA. Although ultrasonography is a radiation-free technique that may provide information about the risk of fracture and bone quality, the reproducibility of this technique and the measurement sites of mainly cortical bone or low-weight-bearing locations may make it unsuitable for monitoring small changes in bone over time. Therefore ultrasound measurements cannot reliably be used to monitor response to osteoporosis therapies. Further data are necessary to validate the clinical utility of ultrasonography.

According to the guidelines of the Scientific Advisory Board of the National Osteoporosis Foundation, bone densitometry is useful in determining which patients might benefit from therapy to protect the skeleton, including patients who have a deficiency of gonadal hormones (postmenopausal women <65 years with one or more risk factors or >65 years regardless of risk factors), post-menopausal fracture, evidence of osteopenia or a vertebral abnormality on radiographs, hyperparathyroidism, or exposure to supraphysiologic doses of glucocorticoids (Table 101-3). Bone densitometry is also used to decide when to commence therapy for osteoporosis and to assess the clinical response to therapeutic interventions.[40] Screening normal pre-menopausal women is not cost-effective.

The World Health Organization has published criteria for osteoporosis on the basis of bone density[1,48]:

- Normal bone density if the T-score is greater than −1.
- Osteopenia (low bone mass) is defined as a bone density measurement between 1 and 2.5 SD below the young-adult mean (T-score between −1 and −2.5).
- Osteoporosis is defined as a bone density measurement less than 2.5 SD below that of young, healthy control subjects (T-score <2.5).

The National Osteoporosis Foundation recommends treatment for all people who have a lumbar spine, hip, or

**TABLE 101-3** Clinical Indications for Bone Densitometry

| |
|---|
| All post-menopausal women <65 yr who have one or more additional risk factors for osteoporosis (besides menopause) |
| All women >65 yr regardless of additional risk factors |
| To document reduced bone density in patients with vertebral abnormalities or osteopenia on radiographs |
| Estrogen-deficient women at risk for low bone density who are considering use of estrogen or an alternative therapy, if bone density would influence the decision |
| Women who have been receiving estrogen replacement therapy for prolonged periods or to monitor the efficacy of a therapeutic intervention or interventions for osteoporosis |
| To diagnose low bone mass in people treated with glucocorticoids |
| To document low bone density in people with asymptomatic primary or secondary hyperparathyroidism |

femoral neck T-score of –2.5 or lower. However, for people who have a bone density between –1 and –2.5, the National Osteoporosis Foundation recommends performing a Fracture Risk Assessment (FRAX) using a computer program that incorporates clinical risk factors for osteoporosis with and without femoral neck BMD. FRAX also provides a 10-year risk of a hip fracture or a major osteoporotic fracture (i.e., hip, proximal humerus, and wrist). The clinical risk factors included in the FRAX program include age, weight, height, history of a fracture as an adult, parental history of a hip fracture, current glucocorticoid use, secondary causes of osteoporosis, alcohol intake of more than two drinks a day, and being a current smoker.[48,49] These risk factors are added to femoral neck T-score for the 10-year fracture risk. In the United States, a 10-year risk of hip fracture of 3% or more or a major osteoporotic fracture of 20% or more is the threshold to recommend treatment. However, the fracture risk threshold for treatment is individualized by country, so it is important to enter the country in which one is practicing medicine.

FRAX has advantages that include easily determined risk factors, global validation, application in specific regions or nations, and scores that pertain to both men and women. However, FRAX has a number of limitations; for example, it can lead to underestimates or overestimates of fracture risk in some patients because it does not include all known risk factors and some risk factors are superficial (e.g., glucocorticoid use is the question, but dose is not evaluated). Such known or suspected risk factors that contribute to fracture risk but are not included in the FRAX algorithm include immobilization, epilepsy, chronic obstructive pulmonary disease, diabetes, and depression. Lastly, the FRAX score is calibrated only for untreated patients, and thus results can be misleading for patients who are already receiving pharmacologic therapy.[48,49]

### Markers of Bone Turnover

The development of sensitive biochemical markers of bone turnover makes it possible to analyze changes in bone formation and resorption at a given point in time and obtain additional information about a patient's risk of bone loss. Only three bone formation markers are currently available. Osteocalcin, a noncollagenous matrix protein in bone, is produced exclusively by osteoblasts; it correlates with histomorphometric bone measurements. In most conditions, bone resorption and formation are tightly coupled, and osteocalcin levels reflect bone turnover. The other markers of bone formation are bone-specific alkaline phosphatase (BSAP), an enzyme that is activated as osteoblasts mature, and amino-terminal propeptide of type I procollagen (PINP), a protein whose synthesis is high in maturing osteoblasts.[50]

Sensitive indicators of bone resorption derived from the degradation of mature collagen include the urine and serum markers of type I collagen cross-links, including amino-terminal telopeptide of type I collagen (N telopeptides, or NTX) or carboxy-terminal telopeptide of type I collagen (C telopeptides, or CTX). Urinary pyridinoline cross-link, NTX, and CTX levels correlate with histomorphometric determinations of bone resorption; these biomarkers increase with estrogen deficiency at menopause and are high in patients with a variety of disorders characterized by accelerated bone turnover, including Paget's disease, osteoporosis, and rheumatoid arthritis.[51,52] Urinary excretion of N telopeptides is inversely related to total hip and spinal bone density and is more reliable than total urinary pyridinolone.[53] A few small prospective studies have found high turnover markers, and low BMD has been associated with incident fracture risk, but these results have not been replicated in larger studies.[54,55] In clinical studies, antiresorptive agents such as estrogen, bisphosphonates, and inhibitor of RANKL induce a significant decrease (30% to 80%) first in markers of resorption and then in bone formation markers, often within 3 to 6 months. Resorption markers decrease before formation markers and correlate with either maintenance of or an increase in BMD. A significant change in bone markers can be observed within months of anti-resorptive therapy, before changes in BMD occur.[55] Both bone formation and resorption marker changes over 6 to 12 months have been found to predict future fracture risk. In a study of alendronate to reduce osteoporotic fractures, patients who had more than a 30% reduction in bone alkaline phosphatase had the greatest reduction in risk for new vertebral and nonvertebral fractures. Interestingly, studies have found that reductions in markers of bone turnover, either resorption or formation markers, are associated with a reduction in fracture risk. However, long-term, prospective studies of large numbers of women are necessary to determine whether selective biochemical markers of bone turnover can predict changes in BMD or fracture risk and whether these tests should be used in standard clinical practice.

Most bone turnover marker data are derived from large studies of anti-resorptive agents. However, a bone-building anabolic agent, PTH, has been approved for the treatment of post-menopausal osteoporosis and glucocorticoid-induced bone loss. PTH stimulates osteoblast activity, and therefore PINP, osteocalcin, and other markers of bone formation increase rapidly, within a few weeks of the initiation of treatment. However, activation of the osteoblast over time results in RANKL production, which stimulates osteoclast activity. With continued PTH treatment, markers of osteoclast activity also increase, reaching levels equal to those of formation markers by 6 months of treatment. Because the overall result is an increase in bone mass, the bone turnover markers during PTH therapy reflect significant bone remodeling on both trabecular and cortical bone surfaces and within the cortex. A few small studies have found that increases in both bone formation and resorption markers predict an increase in bone mass with PTH treatment.[56-58]

### Evaluation for Secondary Bone Loss

The workup for osteoporosis is directed toward excluding secondary causes of bone loss and includes a determination of serum calcium, phosphorus, supersensitive thyroid-stimulating hormone, 25-hydroxyvitamin D (25-OHD), and intact PTH, as well as urine calcium and creatinine levels. Also, a complete blood cell count, alkaline phosphatase and liver function tests, erythrocyte sedimentation rate (in some cases), and serum and urine protein electrophoresis for patients older than 50 years may be necessary (Table 101-4). In men, additional testing for secondary causes of

osteoporosis includes serum testosterone and luteinizing hormone.

Further tests to rule out neoplastic or endocrinologic disorders and a bone biopsy (a decalcified bone specimen is obtained after a double tetracycline label with two different fluorescent labels) should be considered in certain patients with progressive bone loss and in those in whom osteoporosis is unlikely. Identification and appropriate therapy for underlying secondary causes of osteoporosis are important. For example, treatment of vitamin D deficiency is best accomplished with vitamin D supplements. Parathyroidectomy in patients with hyperparathyroidism characterized by hypercalcemia, hypercalciuria, nephrolithiasis, age younger than 50 years, or low cortical BMD (Z-score ≤2) was associated with a large (4% to 12.8%) increase in bone density over 4 years.[59] However, bone density was stable for up to 6 years in patients with mild hyperparathyroidism.[60] In addition, treatment of hyperthyroidism, hypercortisolism, and a variety of other disorders that may cause osteoporosis can produce increments in bone mass. Reduction in the systemic inflammation associated with rheumatic diseases such as TNF-blocking agents for rheumatoid arthritis or ankylosing spondylitis or glucocorticoid-sparing agents for SLE (e.g., azathioprine and mycophenolate mofetil) can also produce increments in bone mass.[61]

# TREATMENT

## Calcium

The goals of therapy for osteoporosis are to reduce bone resorption and enhance bone formation, if possible. Bone loss occurs when the calcium intake and absorption are insufficient to balance the daily calcium losses. Prospective data show that calcium stabilizes bone mass.[62]

Table 101-5 shows the current recommendations for optimal calcium intake for women and men from the 1997 report of the Institute of Medicine to the National Academy of Sciences.[63] In the absence of kidney stones or an underlying disorder of calcium metabolism, these calcium intakes are safe. To prevent negative calcium balance, premenopausal women and men require 1000 mg and postmenopausal women require 1200 mg of total elemental calcium daily.[64] Children have increasing calcium requirements during adolescence, and data show increased bone accretion with increased calcium intake in prepubescent and pubertal children. Calcium carbonate contains 40% elemental calcium and should be taken with meals because of poor absorption in achlorhydric patients in the absence of food. Calcium citrate, which contains 24% elemental calcium, has better bioavailability and is more readily absorbed.[65] It is also absorbed well on an empty stomach in patients with achlorhydria. Recent studies underscore the fact that only recommended daily allowances of calcium and vitamin D are useful for bone health in postmenopausal women and elderly men. Additional supplementation over the recommended daily allowance has resulted in reports of increased cardiovascular disease.[66-68]

## Estrogen

Hormone replacement therapy (HRT) was once the mainstay of treatment in osteoporosis because estrogen inhibits bone resorption, produces a small rise in bone density, and reduces the risk of fracture by approximately 50% in retrospective observational studies. Cardiovascular disease is the leading cause of death in post-menopausal women. Previous data from longitudinal observational studies suggested that estrogen replacement had a beneficial effect on reducing primary and secondary cardiac events in post-menopausal women. However, in 1998, data from the 4-year Heart and Estrogen/Progestin Replacement Study were published.[69] In this study, post-menopausal women with a previous history of heart disease were randomized to receive estrogen (0.625 mg) plus progestin (2.5 mg) or placebo alone. Results showed no reduction in the overall rate of coronary heart disease or cardiac events in the treatment group; in fact, an early increase in risk for cardiac events was noted, possibly related to increased coagulability.[70]

In addition, a large, multicenter, longitudinal study by the Women's Health Initiative (WHI)—in which 162,000 women aged 50 to 79 years were randomized into a placebo group, an HRT group (if the uterus was intact), or an estrogen-only group (if the uterus was absent)—was terminated early because of an increased risk of breast cancer and cardiovascular events. The research goals for the WHI study were to determine the effects of HRT, diet modification, and calcium and vitamin D supplements on heart disease, osteoporosis, and colorectal cancer risk. After a mean follow-up of 5.3 years in an 8.5-year study, the HRT group had an increased risk of seven more cardiac events per 10,000 women taking the drug for a year, eight more invasive breast cancers, eight more strokes, and eight more pulmonary emboli, but six fewer colorectal cancers and five fewer hip fractures.[71]

At this time, the general recommendation is that HRT should be used only for vasomotor symptoms that occur at the time of menopause. When these symptoms abate, it is recommended that estrogen replacement (consisting of combined estrogen and progestin for women with an intact uterus) be stopped because the perceived cardiovascular benefits have not been substantiated and the cardiovascular disease and breast cancer risk make the benefit-to-risk ratio unacceptable for most women. It is important to acknowledge that the estrogen-only arm of the WHI study in women without a uterus did not show an increased risk of heart disease or breast cancer.

If a woman and her physician decide that she is going to take HRT or estrogen alone for vasomotor symptoms, in women with an increased risk of coagulation, transdermal estrogen replacement should be used.

### Selective Estrogen Receptor Modulators

The ideal estrogen replacement therapy would confer the beneficial effects of estrogen on bone and cardiovascular disease without increasing the risk of breast or uterine cancer. Selective estrogen receptor modulators (SERMs) are a nonsteroidal class of drugs that bind to the estrogen receptor and differ from one another in their actions on estrogen-responsive tissues, acting selectively as agonists or antagonists. Tamoxifen, the first available SERM, is an estrogen antagonist that binds to the estrogen receptor and also has estrogen-agonist effects on bone, lipids, clotting factors, and endometrium. Tamoxifen therapy in women with breast cancer produced a small increase in bone density of the spine over 2 years, with no effect on radial bone density, in association with reductions in both low-density lipoprotein and total cholesterol.[72] The Breast Cancer Prevention Trial studied 13,388 women at increased risk for breast cancer, comparing treatment with tamoxifen (20 mg daily) to placebo for 5 years.[73] Tamoxifen reduced the risk of invasive and noninvasive breast cancer by 50%, and a decreased risk of fracture was observed as well: 45% reduction at the hip and 29% at the spine. An increased incidence of low-grade endometrial cancer was noted, but no change occurred in the risk of ischemic heart disease.[73]

Raloxifene,[74] which has been approved by the FDA for the prevention and treatment of osteoporosis, is a SERM that acts as an estrogen agonist on bone, with antagonist effects on the breast and uterus.[75] Raloxifene (60 mg/day over a 2-year study period) increased BMD in the lumbar spine by 2.4%, in the total hip by 2.4%, and in the total body by 2%, with a reduction in fracture risk at 2 years similar to that seen with estrogen or alendronate (5 mg) treatment. During the 2-year study period, raloxifene reduced the incidence of vertebral fractures by nearly 40% in the treated group compared with the placebo group, and fractures recurred in 7.6% of treated women with a previous fracture, compared with 14.3% of those in the placebo group.[76] Endometrial thickness is not increased by raloxifene, but menopausal symptoms may be made worse. Raloxifene decreases low-density lipoprotein cholesterol by 12%, with a nonsignificant increase in high-density lipoprotein cholesterol, but it does not reduce C-reactive protein like estrogen does and was not found to provide cardiovascular protection.[77-80] Raloxifene also decreased the incidence of breast cancer by 76% in patients enrolled in a clinical study of osteoporosis, with breast cancer incidence studied as a secondary endpoint.[74,80] Another study compared tamoxifen and raloxifene, and yet another study evaluated raloxifene versus placebo, in the prevention of breast cancer. The first study reported that both tamoxifen and raloxifene reduced the risk of developing breast cancer, and the second study found that raloxifene reduced the risk of estrogen receptor–positive breast cancer compared with placebo in post-menopausal women.[81,82] At this time, little information is available on the use of raloxifene in men, and thus it is not recommended for male patients.

## Testosterone

Men with osteoporosis, hypogonadism, and symptoms of low libido may benefit from testosterone replacement therapy. This therapy can be administered as testosterone cypionate or enanthate (50 to 400 mg intramuscularly every 2 to 4 weeks) or as a transdermal testosterone replacement patch that is applied to the scrotal area (Testoderm, 4 to 6 mg/day) or elsewhere (Androderm, 2.5 or 5 mg/day).[83] Most studies find that bone mass increases with testosterone replacement when levels of testosterone were low at the initiation of therapy.

## Calcitonin

Calcitonin, a 32 amino acid peptide synthesized by the C cells of the thyroid gland, is a potent inhibitor of osteoclast-mediated bone resorption. Although human and salmon calcitonin are commercially available, salmon calcitonin is most commonly used because of its greater potency. On the basis of data showing an increase in total body calcium, parenteral calcitonin was approved by the FDA for the treatment of osteoporosis in 1984, and calcitonin in a nasal spray was approved for the treatment of post-menopausal osteoporosis in 1995. Parenteral calcitonin (100 IU administered subcutaneously or intramuscularly three times a week or daily) can maintain bone density or produce a small increase in bone mass in the spine and, in some instances, the forearm, particularly in patients with a high bone turnover.[84] Nasal spray calcitonin is absorbed through the nasal mucosa and is approximately 40% as potent as the parenterally administered drug (e.g., 50 to 100 IU of injectable calcitonin is comparable with 200 IU of nasal spray

calcitonin).[85] In osteoporotic women more than 5 years past menopause, nasal calcitonin (200 IU/day) increases spinal bone density by 2% to 3% compared with placebo, with no effect on proximal femur bone mass; higher doses are necessary in the early menopausal period.[85,86] Nasal spray calcitonin therapy in patients with osteoporosis is associated with a 36% reduction in vertebral fractures over 5 years.[86]

The adverse effects of parenteral calcitonin include nausea, flushing, and local irritation at the injection site. Calcitonin given intranasally is well tolerated, with the potential adverse effects of rhinitis and nasal symptoms such as dryness and crusting. Patients treated with parenteral or intranasal calcitonin may also obtain a beneficial analgesic response in the presence of osteoporotic fractures. Recently, calcitonin nasal spray was removed from use in Europe because of a concern that it may increase the risk of prostate cancer in men, but at this time it is still on formularies in the United States.

## Anti-resorptive Drugs

### Bisphosphonates

Bisphosphonates are analogues of pyrophosphate, with a P-C-P rather than a P-O-P core; they are absorbed by the hydroxyapatite of bone and suppress bone resorption. Modification of the side chains can result in the development of a variety of compounds with differing abilities to inhibit bone resorption (Table 101-6). Some bisphosphonates are administered intermittently because of a long skeletal half-life and prolonged retention in bone. These compounds must be taken on an empty stomach because gastrointestinal absorption is less than 10%.

Bisphosphonates have been used for the treatment of patients with Paget's disease of bone, hypercalcemia of malignancy, prevention and treatment of metastatic cancer to bone, and osteoporosis and for the prevention and treatment of glucocorticoid-induced osteoporosis.

Alendronate has been approved by the FDA for the prevention and treatment of osteoporosis. Data in postmenopausal women with bone density at least 2.5 SD below peak bone mass show that alendronate (10 mg/day) compared with placebo produces an 8.8% and 7.8% increase in bone density in the spine and femoral trochanter, respectively, and a 5.9% increase in the femoral neck after 3 years of therapy[87]; smaller rises (2.3% to 4.4%) occur in bone density in the spine and proximal femur in women within 0.5 to 3 years of menopause. Fosamax treatment in women with osteoporosis (T-score <2.5) yields a significant reduction in spine and hip fractures compared with the patients treated with placebo.[88] Alendronate did not reduce the incidence of clinical fractures in women who had low bone mass but not osteoporosis.[89,90] Alendronate treatment is also effective in increasing bone mass in the spine, hip, and total body and helps prevent vertebral fractures and loss of height in men with osteoporosis.[91]

Adverse effects of bisphosphonates include gastrointestinal symptoms such as stomach pain and esophagitis (caution is advised in patients with active symptoms or a history of ulcer disease), myalgias and arthralgias, and, rarely, osteonecrosis of the jaw, along with subtrochanteric fractures with long-term use.[92-96] A once-a-week preparation of alendronate (70 mg) is the most commonly used dose for the treatment of osteoporosis.[93] This preparation increased spinal and hip bone mass similarly to alendronate, 10 mg/day, over a 2-year study period.

Risedronate, another oral bisphosphonate, administered at a dose of 5 mg/day, increased bone mass and reduced the risk of new vertebral fractures 50% better than did placebo.[94-97] Another study performed to assess the effect of risedronate on hip fractures found that women with osteoporosis (defined by a femoral neck T-score of ≤–4.0) had a significant reduction in the risk of hip fracture.[90] Risedronate has been approved for the prevention and treatment of osteoporosis (35 mg once a week and now 150 mg once a month)[91] and for the treatment of Paget's disease (30 mg/day for 2 months, with retreatment if relapse occurs after 2 months).[98,99] Studies show that risedronate may be well tolerated even in patients with mild gastrointestinal symptoms. Bisphosphonates may also reduce bone pain.

Ibandronate, another aminobisphosphonate, is approved for the treatment and prevention of post-menopausal osteoporosis. In phase III studies of ibandronate (2.5 mg/day) versus placebo in post-menopausal women with osteoporosis, incident vertebral fractures were reduced about 50%. Another study compared ibandronate, 150 mg once a month, with the daily 2.5-mg dose and found similar gains in lumbar spine and hip BMD. The FDA approved ibandronate, 150 mg/month, for the treatment of osteoporosis on the basis of this bridging study.[100] Recently, intravenous (IV) ibandronate in a dose of 3 mg every 3 months was found to be similar to ibandronate, 2.5 mg/day, in terms of increasing lumbar spine and hip BMD, and the FDA has approved IV ibandronate for this indication. No data on hip fractures are available for this compound.[101]

Zoledronic acid is approved for the treatment and prevention of post-menopausal osteoporosis.[102] In phase III studies in post-menopausal women with osteoporosis treated with zoledronic acid, 5 mg once a year by IV infusion, the risk of incident vertebral fractures, hip fractures, and other major osteoporotic fractures were reduced by 68%, 40%, and 20%, respectively, compared with the placebo-treated subjects.[102] In another phase III study of patients who had sustained a hip fracture, patients were randomized to

**TABLE 101-6** Inhibition of Metaphyseal Bone Resorption in Vivo by Bisphosphonates

| Chemical Modification | Examples | Anti-resorptive Potency |
|---|---|---|
| First generation: short alkyl or halide side chain | Etidronate | 1 |
| | Clodronate | 10 |
| Second generation: $NH_2$-terminal group | Tiludronate* | 10 |
| | Pamidronate | 100 |
| | Alendronate | 100-1000 |
| Third generation: cyclic side chain | Risedronate | 1000-10,000 |
| | Ibandronate | 1000-10,000 |
| | Zoledronate | 10,0000 |

*Tiludronate has a cyclic side chain, not an $NH_2$-terminal group, but it is generally classified as a second-generation compound on the basis of its time of development and potency.

Modified from Watts NB: Treatment of osteoporosis with bisphosphonates [review], *Endocrinol Metab Clin North Am* 27:419–439, 1998.

either zoledronic acid, 5 mg once a year, or placebo, and after 3 years it was found that the incidence of osteoporotic fractures was significantly less in patients treated with zoledronic acid and that the mortality was lowered compared with the patients treated with placebo.[103] Adverse effects of zoledronic acid include arthralgias and myalgias; however, these adverse events tend to be less frequent with subsequent infusions. In patients undergoing treatment with zoledronic acid, both serum calcium and 25-OHD levels should be monitored and deficiencies should be restored to normal levels before treatment. Zoledronic acid has been approved for the treatment and prevention of post-menopausal osteoporosis (5 mg once a year), osteoporosis in men (5 mg once a year), prevention and treatment of glucocorticoid-induced osteoporosis (5 mg once a year), and Paget's disease. Zoledronic acid at a dose of 4 mg intravenously every 4 weeks is currently approved for the prevention and treatment of bone metastases in patients with breast cancer and multiple myeloma.

### RANK Ligand Inhibitor

Denosumab is a monoclonal antibody that is directed against RANKL and is approved for the treatment of post-menopausal osteoporosis. In phase III studies in post-menopausal women with osteoporosis who were treated with denosumab (60 mg subcutaneously every 6 months) for 36 months or 3 years, the incidence of vertebral fractures, hip fractures, and major osteoporotic fractures was reduced by 68%, 40%, and 20%, respectively.[104] The medication is well tolerated, but adverse events of skin infection requiring hospitalization were higher in subjects treated with denosumab than in subjects treated with placebo. Denosumab is a potent inhibitor of bone resorption with suppression of a marker of osteoclast activity.

CTX-1 is suppressed by nearly 90% a few weeks after each injection; however, the suppression of bone turnover is transient, and bone turnover and bone density return to baseline levels rapidly if the injections of denosumab are discontinued. Post-menopausal women with low bone mass who were treated with alendronate, 70 mg once a week, and then switched to denosumab, 60 mg every 6 months, had a significant gain of BMD compared with subjects who continued to take alendronate.[105] Before treatment with denosumab, serum calcium and 25-OHD should be checked and replaced if needed to achieve normal levels.

### Adverse Events Associated with Potent Anti-resorptive Agents

All potent anti-resorptive agents (bisphosphonates and RANKL inhibitor) have been associated with osteonecrosis of the jaw, a rare disorder in which a small part of the jaw bone dies; this occurrence is associated with exposure of the bone, with loss of the mucosal covering. Although osteonecrosis of the jaw has been reported as an adverse effect of all bisphosphonates and of the RANKL inhibitor, denosumab, the incidence is rare (probably between 1/10,000 to 1/100,000 in persons receiving osteoporosis medication doses); it is more common in patients with cancer who are treated with high doses and with a high frequency. Although the mechanism is still unclear, the American Dental Association recommends that the teeth be examined before the bisphosphonate or other anti-resorptive treatment is initiated and that patients taking these medications should avoid dental procedures if possible, but it is not necessary to stop the treatment if procedures are needed. In addition, the American Dental Association prefers to use the term *anti-resorptive-associated osteonecrosis of the jaw*.[92,106]

Potent anti-resorptive agents (i.e., bisphosphonates and RANKL inhibitors) are also reported to be associated with atypical subtrochanteric fractures. These fractures are somewhat unusual in that they occur below the lesser trochanter in the femur, the incidence is probably about 5 cases/10,000 patient years, they can be bilateral, and they may be related to the duration of the bisphosphonate treatment. At this time, if a patient treated with a potent anti-resorptive agent experiences mid-thigh pain, evaluation for a stress fracture should be performed because it appears that these agents first appear as painful stress fractures that eventually evolve to a displaced fracture. The risk of a subtrochanteric fracture moves to nearly zero with discontinuation of the potent anti-resorptive agents.[107,108]

The development of subtrochanteric fractures in patients taking potent anti-resorptive agents has led the FDA to make a recommendation regarding the duration of treatment of osteoporosis with these agents. The FDA rationalized that the registration trials for the bisphosphonates (alendronate, risedronate, and zoledronic acid) were 3 to 4 years in duration and that the extension trials for alendronate (FLEX), zoledronate acid (Horizon), and risedronate (VERT-MN) ranged from 3 to 10 years in length, and therefore sufficient long-term data existed from patients who were taking the drugs and had stopped taking the drugs to determine the optimal duration of bisphosphonate use for the treatment of osteoporosis. The results of the three extension studies found consistent fracture rates and maintenance of BMD in both active and placebo groups. Based on these data, the FDA recommended that the decisions regarding the discontinuation of bisphosphonates should be based on the individual patient. Younger patients with a normal BMD (T-score of the hip greater than –1.5) after 3 to 5 years of bisphosphonate therapy may be candidates to stop treatment. However, patients with an increased risk of fracture (e.g., patients of an older age, with prevalent fractures, or with BMD in the osteoporotic range [less than –2.0]) may benefit from continued bisphosphonate use.[109-112] An additional analysis by FLEX investigators that evaluated the risk of fracture in subjects treated with alendronate, 10 mg a day for about 9 years, compared with alendronate for 4.5 years and then placebo for 5 years, and concluded that subjects with a femoral neck BMD of greater than –2 were unlikely to benefit from additional treatment with a bisphosphonate after 4 years. However, subjects with a femoral neck BMD of less than –2 with fractures or less than –2.5 without fractures may benefit from continued bisphosphonate treatment.[113]

## Parathyroid Hormone

Beginning in the 1980s, small randomized studies determined that the 1-34 fragment of the PTH protein can significantly increase bone mass in the spine, with small losses or no gain at the skeletal sites rich in cortical bone.[114,115] In

2001 a recombinant human PTH (rhPTH) composed of the 34 amino acids from the amino-terminal end of the hormone, known as *Forteo*, was approved for the treatment of postmenopausal osteoporosis. In a large international, multicenter study, osteoporotic women who had sustained a fracture were randomized to receive rhPTH at a dose of 20 μg/day or 40 μg/day or placebo for an average of 21 months. Lumbar spine bone mass increased between 9% and 13% in the subjects treated with rhPTH compared with the subjects treated with placebo; hip bone mass also increased slightly. Most important, the risk of new vertebral fractures was reduced nearly 70% in both sets of subjects treated with rhPTH, and nonvertebral low-trauma fractures were reduced nearly 50% compared with the subjects treated with placebo.[116] Initially this study was supposed to continue for 3 years; however, it was stopped at approximately 21 months because of pre-clinical evidence of malignant bone tumors in animal models. Additional studies of osteoporosis in men treated with rhPTH 1-34 have reported significant gains in bone mass.[107] Forteo is given as a daily injection. Persons using this medication may experience headache, nausea, and flushing with initiation of treatment, but these adverse effects generally become less severe after a few weeks.

A number of recent studies have evaluated whether rhPTH 1-34 or rhPTH 1-84 is more effective in combination with an anti-resorptive agent (either bisphosphonates or raloxifene) than rhPTH alone in increasing BMD and reducing fractures.[117,118] Interestingly, two studies found that the combination of PTH and alendronate was less effective in stimulating bone gain at the lumbar spine in both osteopenic women and men over 1 to 1.5 years.[108,109] However, in a recent study of post-menopausal women with osteoporosis who were treated with PTH alone, denosumab alone, or a combination of PTH and denosumab for 1 year, it was found that the combination treatment increased lumbar spine BMD by 9.1% and total hip BMD by 4.9%, which was significantly greater than either treatment alone.[119]

Continued treatments for an additional 12 months with PTH and denosumab further increased lumbar spine BMD to 12% and total hip BMD to 6%, and with 1 year of additional denosumab, bone mass at both the lumbar spine and total hip remained stable.[120]

PTH stimulates new bone formation, increases bone mass, and reduces new vertebral and nonvertebral fractures, but when the medication is discontinued, the bone gained is rapidly lost. Black and colleagues[121] performed a study in which patients were given PTH for 1 year, followed by 1 year of alendronate treatment. Interestingly, the BMD gain after 1 year of PTH was about 6%; when followed by alendronate, nearly 6% BMD was gained at the spine. These data suggest that although PTH is an effective monotherapy for increasing bone mass, especially in the spine, the gain in BMD should be maintained with a potent anti-resorptive agent for a number of years. Recent data from Deal and colleagues[122] indicate that lumbar spine BMD gained after PTH therapy is maintained with raloxifene treatment.

PTH is the first bone anabolic agent approved for the treatment of osteoporosis. Patients give themselves a subcutaneous injection daily for 18 to 24 months. Other routes of administration are now being studied, including an intranasal route and a skin patch.

## New Medications in Clinical Development

### Odanacatib

Cathepsin K is an enzyme released from osteoclasts that degrades collagen I in the bone matrix. Phase II and III clinical trials in subjects with low bone mass or osteoporosis have been completed. A phase II study demonstrated that treatment with odanacatib, 50 mg weekly,[123] increased lumbar spine bone mass by 5.5% and total hip BMD by 3.2% over 2 years, and biochemical markers of bone turnover demonstrated dose-related changes. Discontinuation of the medication resulted in a rapid increase in bone turnover markers, and after 12 months, the bone mass had returned to baseline values.[124] A recent phase III study (LOFT) of odanacatib, 50 mg a day, versus placebo, showed that after 5 years there was a 54% reduction in relative risk of new or worsening vertebral fractures, a 47% relative risk reduction in clinical hip fractures, a 23% relative risk reduction of clinical nonvertebral fractures, and a 72% reduction n clinical (painful) vertebral fractures.[125] In addition, treatment with odanacatib led to a progressive increase over 5 years in BMD at the lumbar spine and total hip; compared with the placebo group, the change in BMD from baseline to 5 years was 11.2% for the lumbar spine and 9.5% for the total hip. The rates of adverse events overall in the LOFT trial were balanced between the patients treated with odanacatib and placebo. However, morphea-like skin lesions and atypical femoral fractures were observed more often in the odanocatib group than in the placebo group.[125] Odanacatib treatment for osteoporosis is currently under review by the FDA.

### Romosozumab

Romosozumab is a monoclonal antibody that inhibits the Wnt signaling antagonist sclerostin and is currently in clinical development for the treatment of osteoporosis. Sclerostin, which is produced mainly by osteocytes within the bone and then is transported through the osteocyte canalicular network to the bone surface, inhibits osteoblast maturation. Treatment with romosozumab in pre-clinical studies of estrogen-deficient bone loss found restoration of bone mass to the baseline levels.[126] A recent phase II clinical trial reported that in post-menopausal women with low bone mass, a monthly treatment with romosozumab for 12 months increased lumbar spine bone mass by 12%, femoral neck bone mass by 4%, and total hip bone mass by 4%; this increase was significant greater than with treatment with either rhPTH (1-34) or alendronate.[127] Phase III clinical studies are now ongoing to determine if treatment with romosozumab can reduce incident hip fractures in postmenopausal women with osteoporosis.

## Vitamin D

Physiologic doses of vitamin D are important to ensure normal bone mineralization. Persons 50 years and older should take at least 600 to 1000 IU of vitamin D daily as a multivitamin or combined with a calcium supplement. Hypovitaminosis D is common in the elderly population, with one study demonstrating that 57% of patients in a general medical ward were deficient in vitamin D.[128] Low

vitamin D levels increase the risk of bone loss and fracture. LeBoff and colleagues[42] found that 50% of patients admitted with acute femur fractures had vitamin D deficiency (25-OHD level <12 ng/mL), and 36.7% had secondary hyperparathyroidism. Data show seasonal variations in vitamin D levels; low 25-OHD levels during the winter and spring are associated with decreases in bone density. The importance of vitamin D to skeletal health was shown when elderly women in a nursing home who were treated with only 800 IU/day of vitamin D had a 40% reduction in incident hip fractures over 18 months compared with placebo-controlled subjects.[129] Although this dramatic effect on fractures in an elderly population may represent a correction of vitamin D insufficiency, this study underscores that adequate vitamin D replacement can effectively diminish fractures in older persons. Insufficient calcium and low 25-OHD levels are common in ambulatory patients and should be identified and treated before anti-resorptive or other therapies for osteoporosis are initiated.

Although 200 IU of vitamin D prevents bone loss in the spine, data show that a higher daily intake (800 IU) is necessary to diminish bone loss in the hip during the winter and spring. Daily treatment with 700 IU of cholecalciferol and 500 mg of calcium carbonate reduced the rate of bone loss significantly in the femoral neck, spine, and total body and decreased the incidence of nonvertebral fractures by 50%.[130] Therefore, to maintain skeletal health, patients require a vitamin D intake that results in a serum 25-OHD level of at least 30 ng/mL. To achieve this level in patients who do not receive regular sunlight, the daily intake of vitamin D needs to be higher. Replacement with 1,25-dihydroxyvitamin D ($1,25[OH]_2D$) is not recommended because hypercalcemia and hypercalciuria are common and require regular and costly monitoring.

### Preventive Measures

Because bone loss is not completely reversible with existing therapies, prevention is essential for optimizing skeletal health. Strategies directed at increasing peak bone mass, reducing risk factors for bone loss (e.g., hypogonadism, decreased body fat, cigarette smoking, inactivity, and excessive alcohol intake), and reversing the secondary causes of osteoporosis may prevent bone loss. Patients should be advised to consume adequate vitamin D and calcium and participate in a regular weight-bearing exercise program. Weight-bearing exercise increases muscle strength and may stabilize or modestly increase bone density. Emerging data show that increased calcium intake and exercise can add to bone accretion during adolescence and that interventions such as vitamin D and calcium supplementation can reduce fractures in older patients. Thus it is highly recommended that preventive strategies or therapies be instituted at any age to diminish the risk of fractures, which rises exponentially with age.

## GLUCOCORTICOID-INDUCED OSTEOPOROSIS

Bone loss is a common sequela of therapy with glucocorticoids,[131] and glucocorticoid use increases the risk of fractures in patients with rheumatic diseases.[20] The severity of the bone loss in patients treated with glucocorticoids varies, with an approximately 3% to 20% decrease in bone density over 1 to 2 years. Glucocorticoid therapy is associated with increased fractures of the ribs and vertebrae, sites that contain predominantly trabecular bone, and it triples the risk of hip fracture in one-third of patients after 5 to 10 years of treatment.[132,133] In adults, alternate-day glucocorticoid therapy does not prevent bone loss. In patients with rheumatic diseases, concerns over the development of glucocorticoid-induced osteoporosis often limit the dose and duration of glucocorticoid therapy.

The lowest possible glucocorticoid dose should be used, along with general preventive strategies such as a regular weight-bearing exercise program, adequate calcium and vitamin D intake, and reduction of other risk factors that might contribute to the development of osteoporosis. However, data show that even patients taking 5 mg/day of prednisone have accelerated bone loss compared with control subjects. General prophylactic measures to prevent glucocorticoid-induced osteoporosis are shown in Table 101-7. Intestinal calcium absorption is impaired in patients treated with glucocorticoids, and early studies showed that this impairment could be offset with vitamin D (40 to 100 μg/day two to three times a week) or 25-OHD, which produced an increase in bone density of the forearm. However, the administration of supraphysiologic doses of vitamin D requires careful monitoring of the serum and urinary calcium concentrations in patients at high risk for bone loss (with a normal urinary calcium level and no history of nephrolithiasis). An alternative approach in patients at risk for osteoporosis and receiving long-term

**TABLE 101-7** Recommendations for the Prevention and Treatment of Glucocorticoid-Induced Osteoporosis

**Prevention**

Patients starting GC therapy at a dose equivalent to prednisone ≥5 mg/day for 3 mo or longer should:

- Modify risk factors for osteoporosis (i.e., stop smoking and decrease excessive alcohol consumption)
- Start regular weight-bearing physical exercise
- Initiate intake of calcium (total 1500 mg/day) and vitamin D (400-800 IU/day)
- Consider BMD testing to predict risk of fracture and bone loss
- Initiate bisphosphonate therapy (alendronate, 5 mg/day or 35 mg/wk, or risedronate, 5 mg/day or 35 mg/wk)

**Treatment**

Patients receiving long-term GC therapy should be tested for osteoporosis using BMD measurement. If the T-score is <–1, consider:

- Risk factor modification, including reducing risk of falls
- Regular weight-bearing physical exercises
- Calcium and vitamin D supplementation
- Replacement of gonadal steroids, if deficient
- Bisphosphonate therapy (alendronate, 10 mg/day or 70 mg/wk, or risedronate, 5 mg/day or 35 mg/wk); if bisphosphonates are contraindicated or not tolerated, consider calcitonin as a second-line agent, intravenous bisphosphonate (pamidronate or zoledronate), or parathyroid hormone 1-34
- Repeat BMD measurement annually or biannually

BMD, Bone mineral density; GC, glucocorticoid.

Modified from Recommendations for the prevention and treatment of glucocorticoid-induced osteoporosis: 2001 update, *Arthritis Rheum* 44:1496–1503, 2001.

glucocorticoid therapy is to raise the 25-OHD level into the upper-normal range (>30 ng/mL) to ensure adequate intestinal calcium absorption. This goal can usually be accomplished by administering vitamin D at 1000 to 2000 IU/day.

Because of the enhanced bone resorption in patients treated with glucocorticoids, investigators have examined the effects of inhibitors of bone resorption. The use of bisphosphonates in patients receiving chronic glucocorticoid therapy is beneficial for both the prevention and treatment of osteoporosis. The use of alendronate, 5 or 10 mg/day for 1 year in patients receiving glucocorticoid therapy, increased lumbar spine BMD by 2.1% and 2.9%, respectively, and increased femoral neck BMD by 1.2% and 1%, respectively ($P$ <0.001).[134] After 1 year of treatment, an insignificant reduction in new vertebral fractures occurred, but after 2 years of treatment, a nearly 40% reduction in new vertebral fracture risk occurred. Risedronate, 5 mg/day, was also effective in the prevention and treatment of glucocorticoid-induced bone loss.[134] Recent studies of zoledronic acid (5 mg IV/year) versus risedronate (5 mg/day) and teriparatide (20 μg/day) versus alendronate (10 mg/day) for 18 months indicated that both zoledronic acid and teriparatide improved bone mass more than the comparator, and subjects treated with teriparatide had a significant vertebral fracture risk reduction[135,136] in glucocorticoid-treated patients. Combination studies of rhPTH 1-34 with HRT were also found to be more effective than HRT alone in persons with glucocorticoid-induced osteoporosis.[137] No difference between treatments was observed with regard to fracture data; however, quantitative CT of the lumbar spine, a measure of trabecular bone only, found a nearly 35% increase in patients treated with PTH compared with the estrogen-only group after 12 months of therapy.[138]

Men taking glucocorticoids can experience a lowering of testosterone levels.[139] Men taking glucocorticoids are generally asymptomatic, but if they have evidence of low serum testosterone levels and symptoms of low libido, they can be safely treated with testosterone. Bone mass increases have been observed in men taking glucocorticoids who had low testosterone levels and were treated with testosterone.[140] However, because of the risks associated with testosterone treatment, it is more prudent to treat these patients with a bisphosphonate medication.

To prevent bone loss in patients with pulmonary diseases who require glucocorticoid therapy, treatment with inhaled glucocorticoids has been studied.[141] Inhaled glucocorticoids appear to uncouple bone turnover and increase bone loss; however, this effect is dose dependent. Less than 800 μg/day of inhaled budesonide dipropionate does not increase the risk of osteoporosis, but more than 800 μg/day does increase the risk. New inhaled steroids are more potent than older ones; for instance, Advair, 200 μg/day, is equivalent to nearly 5 mg/day of prednisone.[142] Therefore patients using steroid inhalers on a long-term basis should be screened for bone loss. Because patients who take glucocorticoids may lose a dramatic amount of bone, it is important to monitor the efficacy of a treatment intervention, assess the need for further diagnostic evaluation for other causes of bone loss, and consider alternative treatment strategies if a given therapy is ineffective in preventing bone loss or fractures. In patients at increased risk of fracture, therapy with a potent bisphosphonate or daily PTH injections are highly recommended to slow bone loss and the rate of new fractures.[143-145]

An unresolved question regarding the treatment and prevention of glucocorticoid-induced bone loss is how long to wait before initiating treatment with bone active agents after the discontinuation of the glucocorticoid treatment. It is generally recommended that a BMD measure be obtained 3 to 6 months after the discontinuation of chronic glucocorticoid use and that a decision regarding additional treatment be made on the basis of the BMD measure and any recent history of a fragility fracture.

## OSTEOMALACIA

Osteomalacia is characterized by impaired mineralization of bone matrix. Calcium, phosphate, and vitamin D are necessary for the mineralization of bone. Normally, a steep inverse relationship exists between the serum calcium and PTH concentrations. A small decrease in the serum calcium concentration leads to a rise in PTH release, which promotes distal renal calcium reabsorption, proximal tubulorenal phosphorus excretion, and resorption of calcium from bone. Vitamin D is produced in the skin in the presence of ultraviolet light or is absorbed in the intestine from dietary or supplemental sources. Activation of vitamin D to 25-OHD occurs in the liver, and activation to $1,25(OH)_2D$ occurs in the proximal tubules of the kidney. PTH, hypocalcemia, and hypophosphatemia stimulate the renal 1-hydroxylase enzyme that converts 25-OHD to $1,25(OH)_2D$, which in turn indirectly enhances intestinal calcium absorption.[146]

Osteomalacia results from reduced availability of calcium or phosphate for incorporation into the hydroxyapatite of bone or from deficient absorption or activation of vitamin D.[147] The term *rickets* applies to the defective mineralization of bone and the cartilaginous growth plate in growing children. As shown in Table 101-8, osteomalacia or rickets may result from decreased availability of vitamin D as a consequence of insufficient ultraviolet light exposure, insufficient vitamin intake, or malabsorption in patients with gastrointestinal or biliary disorders. Reduced levels of 25-OHD are caused by severe liver disease, increased renal excretion of vitamin D metabolites due to nephrotic syndrome, or accelerated metabolism of 25-OHD caused by anticonvulsant drugs. Decreased activation of $1,25(OH)_2D$ is seen in patients with renal insufficiency as a result of increased phosphate levels; the resultant lower ionized calcium levels lead to secondary or tertiary hyperparathyroidism.

A careful history is important in the diagnosis of osteomalacia or vitamin D insufficiency. For example, a history of a malabsorptive process such as gastrectomy, intestinal resection, sprue, primary biliary cirrhosis, or pancreatic deficiency may lead to the identification of vitamin D deficiency and osteomalacia.[147] Patients with osteomalacia may present with generalized pain involving the pelvis, spine, ribs, or lower extremities or with skeletal deformities such as bowing of the long bones, kyphoscoliosis, or pelvic abnormalities. Another clinical sign of osteomalacia in adults is proximal muscle weakness, which may result in an antalgic or waddling gait and difficulty ambulating.

Pain may be elicited by deep palpation of the tibia, ribs, or pubic ramus.[147] One of the radiographic signs of osteomalacia is the presence of pseudofractures, or Looser's

**TABLE 101-8** Causes of Osteomalacia and Rickets

| |
|---|
| **Vitamin D Deficiency or Dysfunction** |
| Reduced Availability |
| Nutritional deficit |
| Reduced exposure to ultraviolet light |
| Malabsorption (gastrointestinal or biliary disease or surgical resection) |
| Alteration in Metabolism |
| Reduced 25-hydroxyvitamin D from liver or gastrointestinal disease, nephrotic syndrome, or use of anticonvulsant drugs |
| Reduced 1,25-dihydroxyvitamin D from renal disease or vitamin D–dependent rickets type I |
| Alteration in Action on Target Tissues |
| Vitamin D–dependent rickets type II |
| **Phosphate Deficiency** |
| Decreased availability—dietary deficiency and phosphate-binding antacids |
| Decreased renotubular phosphate reabsorption |
| Familial—X-linked hypophosphatemic rickets and adult-onset vitamin D–resistant osteomalacia |
| Acquired—hypophosphatemic osteomalacia (phosphate diabetes) and oncogenic osteomalacia |
| Generalized renotubular disorders |
| **Acidosis** |
| Renotubular acidosis |
| Ureterosigmoidostomy |
| Carbonic anhydrase inhibitors (acetazolamide) |
| **Miscellaneous Mineralization Defects** |
| Inhibitors of mineralization—fluoride, bisphosphonates (e.g., etidronate), and chronic renal failure (aluminum) |
| Hypophosphatasia |

Modified from LeBoff MS, Brown EM: Metabolic bone disease. In Hare JW, editor: *Signs and symptoms in endocrine and metabolic disorders,* Philadelphia, 1986, JB Lippincott, pp 239–260.

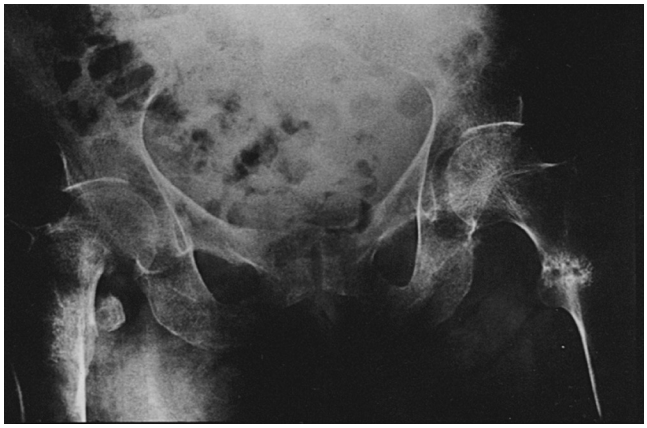

**Figure 101-2** Osteomalacia and fractures in a 65-year-old woman with malabsorption. Shown are a pseudofracture of the left lesser trochanter and an avulsion of the right lesser trochanter. This patient also had previous bilateral pubic rami fractures.

zones, which are transverse lines of rarefaction through the cortices, with incomplete healing in the ribs, scapulae, long bones (Figure 101-2), or pubic rami. Pseudofractures, however, may be indistinguishable from fractures associated with osteogenesis imperfecta or Paget's disease. Other radiographic findings in osteomalacia are vertebral fractures or protrusio acetabuli. Vitamin D deficiency may result in irreversible cortical bone loss.[147] In subtle cases of osteomalacia, a bone biopsy with a double tetracycline label may be necessary; characteristic histomorphometric findings in this disorder include increased osteoid and delayed mineralization of bone.

Rickets causes abnormalities of the epiphyseal growth plate; the clinical signs include an inability to ambulate, growth disturbances, bowing of the long bones, and short stature. Bony deformities of the skull and ribs may develop, with widened cranial sutures (craniotabes), thickened costochondral junctions (rachitic rosary), or indentation of the margins of the ribs (Harrison's grooves).

The biochemical parameters in patients with osteomalacia reflect the underlying pathophysiologic process and the compensatory biologic responses. In vitamin D deficiency states, the serum calcium levels are usually normal or slightly decreased because PTH levels rise rapidly as a compensatory response to impaired calcium absorption.[148] In renal insufficiency phosphate retention, impaired renal production of $1,25(OH)_2D$, hypocalcemia, and skeletal resistance to PTH are thought to lead to the development of hyperparathyroidism and resultant renal osteodystrophy, mixed osteomalacia, and osteitis fibrosa cystica.[149] In addition, aluminum intoxication may present with pure osteomalacia or adynamic bone disease.[148,150] Chronic vitamin D deficiency may increase the secretory demands of the parathyroid glands, thereby producing secondary or, in some instances, tertiary hyperparathyroidism. In patients with osteomalacia who do not have hepatobiliary disease, alkaline phosphatase levels are often elevated.[151]

Osteomalacia may be associated with a deficiency of phosphate, principally in patients with decreased renotubular reabsorption of phosphate. Familial hypophosphatemic vitamin D–resistant rickets in children or osteomalacia in adults usually presents with renal phosphate leak, hypophosphatemia, rachitic or osteomalacial changes, and inappropriately normal or low-normal $1,25(OH)_2D$ level for the degree of hypophosphatemia. This X-linked dominant disorder may present in young children with the inability to walk, followed by progressive bowing and skeletal deformities, without signs of proximal myopathy. The genetic locus for X-linked hypophosphatemic rickets has been mapped to Xp22.1, and the gene is named *PHEX* (phosphate-regulating gene with homology to endopeptidases on the X chromosome).[151]

Oncogenic osteomalacia or rickets is a vitamin D–resistant process associated with certain neoplasias, principally small, benign mesenchymal or endodermal tumors and, infrequently, certain malignant tumors (e.g., multiple myeloma and prostatic, oat cell, and breast carcinomas).[152,153] Such patients typically present with decreased renotubular phosphate reabsorption, hypophosphatemia, muscle weakness, diminished $1,25(OH)_2D$ levels, and normocalcemia. The benign tumors tend to be small and difficult to identify on physical examination or radiographs. Surgical removal of these tumors results in a rise in phosphate and $1,25(OH)_2D$ levels and resolution of the skeletal process. Osteomalacia may also be associated with generalized renotubular disorders and the use of certain drugs that contain inhibitors of mineralization (e.g., fluoride, etidronate, and aluminum). The evaluation of a patient suspected of having osteomalacia is outlined in Table 101-9.

Osteomalacia is often a treatable disease, but the diagnosis may be overlooked. Vitamin D deficiency can be treated with physiologic doses of vitamin D, but higher

doses (1000 to 2000 IU/day) may hasten the healing of bone. In the presence of intestinal malabsorption, and until the underlying malabsorptive process is corrected, large doses of vitamin D (50,000 IU once a week to three or more times a week) are often required. Careful monitoring of the serum and urinary calcium levels and 25-OHD concentrations is necessary to prevent vitamin D intoxication. Use of the active metabolite of 25-OHD (Calderol) occasionally may be necessary in resistant patients or in persons with severe liver disease who cannot achieve activation of this metabolite. The potential advantages of using 25-OHD are more stable bioavailability, a shorter half-life, and greater potency than the parent compound,[148] although the cost is greater.

In patients with hypophosphatemia and disorders of renotubular phosphate reabsorption, mineralization of bone occurs with phosphate therapy and moderately high doses of $1,25(OH)_2D$, with the latter being necessary to prevent the secondary hyperparathyroidism associated with phosphate therapy. In patients affected by renal insufficiency or failure, a phosphate binder (calcium acetate or calcium carbonate) should be used after meals to decrease intestinal phosphate absorption. Calcium citrate therapy should not be used because it augments aluminum absorption. In persons with renal failure, $1,25(OH)_2D$ therapy administered orally[148,154] (or intravenously in some patients undergoing dialysis) suppresses parathyroid cell secretion and proliferation; a threefold elevation of the PTH level is advocated by some investigators to prevent adynamic bone disease.[149] Analogues of $1,25(OH)_2D$ that do not produce hypercalcemia but decrease levels of PTH are now available and may be useful in patients with renal insufficiency.

## PAGET'S DISEASE OF BONE

Paget's disease of bone affects approximately 2% to 3% of the population older than 50 years and is uncommon in persons younger than 40 years.[155] Paget's disease is characterized by enhanced resorption of bone by giant, multinucleated osteoclasts, followed by the formation of disorganized woven bone by osteoblasts. The resultant bone is expanded, weak, and vascular, and thus affected bones may become enlarged and deformed, and the overlying skin may feel warm to the touch.[156]

### Cause

The cause of Paget's disease is uncertain, although data showing the presence of viral inclusion particles in giant pagetic osteoclasts support a viral cause, possibly associated with measles, respiratory syncytial, or canine distemper virus. Paget's disease tends to aggregate in families in an autosomal dominant pattern, and in 40% of patients, at least one other family member is affected.[157] Recently, in a family with juvenile Paget's disease, the disease was found to be associated with a polymorphism in the OPG allele.[158] Studies of additional families with this mutation may lead to the discovery of the cause of Paget's disease.

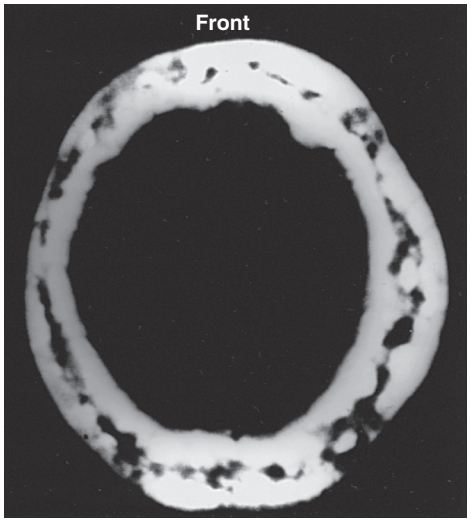

**Figure 101-3** Paget's disease of the skull in a woman with signs of increasing head size and progressive hearing loss. The alkaline phosphatase level was 2100 U/L. This computed axial tomogram shows marked thickening of the inner and outer skull tables, with osteoblastic pagetoid changes. An audiologic evaluation revealed bilateral hearing loss.

### Clinical Features

Many patients with Paget's disease are asymptomatic, and the disease is detected by the incidental finding of an elevated alkaline phosphatase level or a characteristic radiographic abnormality. Other patients present with a range of symptoms that include bone pain; skeletal deformities (e.g., bowing of long bones, an enlarged skull, and pelvic alterations); pathologic fractures; increased cardiac output (with extensive disease); and nerve compression. Paget's disease typically includes a lytic phase, a combined lytic and blastic phase, and a sclerotic or "burned out" phase occurring late in the disease process.

Radiographic signs of the three stages of Paget's disease may be present at different sites in the same patient.[157] The skeletal sites commonly involved in persons with Paget's disease include the skull (Figure 101-3), vertebrae, pelvis, sacrum, and lower extremities. Degenerative joint disease may develop adjacent to the bones and cause pain that may obscure the symptoms associated with Paget's disease.[157] Ten percent to 30% of patients with Paget's disease may experience fractures that present initially as asymptomatic or painful short fissure fractures traversing the bony cortex (Figure 101-4). Complete fractures of the bones such as the "chalk stick" fracture also occur; fractures of the long bones may be a serious complication because the increased vascularity of pagetic bone may lead to excessive blood loss.

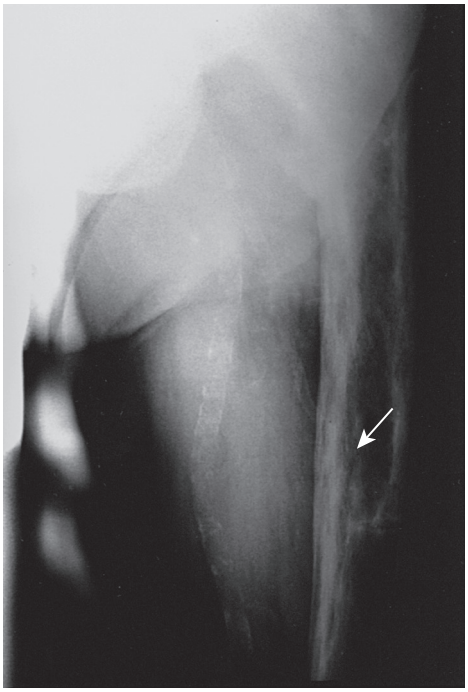

**Figure 101-4** Paget's disease of the proximal femur. Note the coarse trabeculae, thickened cortices, lateral fissure fracture, and expanding lytic region characteristic of the "blade-of-grass" lesion *(arrow)*.

Healing of fractures in pagetic bone usually occurs normally, although cases of nonunion have been reported. A rare complication of Paget's disease of bone is sarcomatous degeneration in less than 1% of patients (with osteogenic sarcomas or, less commonly, fibrosarcomas or chondrosarcomas); these patients generally have a poor prognosis. The development of a sarcoma may be heralded by the presence of a soft tissue mass, localized pain, and a rise in the alkaline phosphatase level.

Neurologic symptoms generally result from compression of the nerves by pagetic bone. Hearing loss is common and is caused by sensory loss and conduction abnormalities due to pagetic involvement of the bones of the inner ear. Paget's disease of the skull may also produce ocular and other cranial nerve palsies. Compression of the base of the skull may lead to basilar invagination, cerebellar dysfunction, or obstructive hydrocephalus, with symptoms of nausea, ataxia, incontinence, gait disturbances, and dementia. Neurologic compromise of the thoracic or lumbar spine may lead to spinal cord compression or, in the latter instance, cauda equina syndrome.

## Laboratory Findings

Biochemical indices in patients with Paget's disease usually show normal serum calcium and phosphate levels, although hypercalcemia may develop with immobilization when an uncoupling of bone resorption and formation occurs. Patients with Paget's disease may also be hypercalcemic if they coincidentally acquire primary hyperparathyroidism, which can further increase bone remodeling and worsen the disease process. Secondary hyperparathyroidism may develop in approximately 10% to 15% of patients with Paget's disease, presumably because of inadequate calcium intake to meet the skeletal demands of the heightened bone remodeling.[157]

**TABLE 101-10** Indications for Treatment of Paget's Disease of Bone

| |

| Skull involvement |
| Neurologic compromise |
| Periarticular disease |
| Prevention of progression of Paget's disease |

Alkaline phosphatase levels of bone origin (bone-specific alkaline phosphatase; BSAP) are commonly elevated in patients with significant Paget's disease because of the increased osteoblastic activity combined with bone breakdown. In the absence of liver disease, the alkaline phosphatase level typically correlates with the extent of the pagetic involvement of bone, although it may be more elevated in Paget's disease of the skull (see Figure 101-3).

Unexpectedly, circulating osteocalcin levels do not reflect disease activity in patients with Paget's disease as well as do BSAP levels. Markers of bone resorption such as urinary collagen cross-links like N telopeptides and C telopeptides are also elevated in persons with active Paget's disease. Other laboratory abnormalities in patients with Paget's disease include hypercalciuria, hyperuricuria, and hyperuricemia, possibly related to the increased turnover of osteoclasts. Serum uric acid levels should be measured periodically because of the association of Paget's disease with gouty arthritis.

## Diagnosis

Bone scans are valuable tools for assessing the extent of Paget's disease and are therefore useful as part of the initial evaluation.[155,157] As diagnostic tests, however, bone scans in general are sensitive but not specific for a number of skeletal processes. Radiographs show characteristic radiologic findings such as transverse lucent areas, osteoporosis circumscripta, enlargement of the bones, expanding lytic changes, the "blade-of-grass" lesion shown in Figure 101-4, thickened cortices, a coarse trabecular pattern, or sclerotic changes.

In patients with involvement of the skull and changes in mental status, a skull radiograph, MRI, or quantitative computed tomography may be useful to diagnose platybasia and flattening of the base of the skull, basilar invagination, or the infrequent complication of hydrocephalus. Audiologic evaluation may reveal hearing loss in patients with pagetic involvement of the skull.

## Treatment

The indications for treatment of Paget's disease (Table 101-10) include pain, hypercalcemia, fractures, high-output cardiac failure (a rare feature), and neurologic compromise.

Therapy can also be used to prevent the progression of deformity or risk of nerve compression when there is pagetic involvement of the skull, a vertebral body, or a weight-bearing bone (femur) or when disease is present adjacent to a major articular joint.

Treatment of symptomatic Paget's disease is usually directed at suppression of the enhanced bone resorption and skeletal turnover with calcitonin or bisphosphonates.[148,150] Response to therapy is monitored by the reduction of symptoms and maintenance of the alkaline phosphatase level in a mid-normal range, with retreatment once values rise 25% above normal.

### Calcitonin

Salmon calcitonin and human calcitonin inhibit the function of osteoclasts, which are active in the pagetic process; both types of calcitonin preparations come in an injectable form and are approved by the FDA for patients with Paget's disease.[159] Salmon calcitonin therapy is usually initiated at a low dose to ensure patient tolerance and then increased to a daily dose of 100 Medical Research Council units (intramuscularly or subcutaneously). After 6 months of therapy, the patient may receive a maintenance dose of 50 to 100 Medical Research Council units daily.[139] Approximately two-thirds of patients show a decrease in alkaline phosphatase levels of 50% or more in 2 to 6 months. Some patients experience resistance to the effects of calcitonin, which can be reversed in some instances by switching from salmon calcitonin to human calcitonin. Calcitonin has also been linked to an increased risk of cancer. The European Committee for Medicinal Products (CHMP) for human use found that "a higher proportion of patients treated with calcitonin for long periods of time develop cancer of various types, compared with patients taking placebo." The increase in cancer rates ranged from 0.7% for oral formulations to 2.4% for the nasal formulation. CHMP removed the nasal formulation from the market in Europe because its only indication was for osteoporosis. Because of the increased risk of cancer, the European Medicines Agency recommended that calcitonin (by injection) be used only on a short-term basis for three conditions for which it had previously been approved in the European Union: Paget's disease, acute bone loss resulting from sudden immobilization, and hypercalcemia caused by cancer. Currently the United States has put no restrictions on the duration of use of calcitonin.

### Bisphosphonates

Several bisphosphonates are currently approved by the FDA for the treatment of Paget's disease, including etidronate disodium, pamidronate, alendronate, tiludronate disodium, risedronate, and zoledronic acid.

- Etidronate disodium in tablet form is available in 200- to 400-mg doses. It is approved as a once-daily treatment for 6 months; the higher dose (400 mg) is more commonly used. No food, beverage, or medications should be consumed for 2 hours before and after taking this drug. The course should not exceed 6 months, but repeat courses can be given after rest periods, preferably of 3 to 6 months' duration.[160]
- Pamidronate disodium is available in intravenous form. The approved regimen consists of a 30-mg infusion that must be administered over 4 hours for 3 consecutive days, or 60 mg over 2 to 4 hours for 2 or more consecutive days.[161]
- Alendronate sodium is available as a 40-mg tablet that is taken once daily for 6 months; patients should wait at least 30 minutes after taking this drug before eating any food, drinking anything other than tap water, taking any medication, or lying down (the patient may sit, however).[162]
- Risedronate sodium is available as a 30-mg tablet taken once daily for 2 months; patients should wait at least 30 minutes after taking the drug before eating any food, drinking anything other than tap water, taking any medication, or lying down (the patient may sit, however).[163]
- Zoledronic acid is available as a 5-mg IV infusion. A single dose of 5 mg over 15 minutes is sufficient for 2 years. Adverse effects can include fatigue, anemia, muscle aches, swelling of the feet, and flu-like symptoms after the first infusion.[164]

In addition to anti-resorptive therapies, NSAIDs and aspirin are useful modalities to alleviate the joint pain and other symptoms that result from degenerative joint disease. Finally, surgical intervention is sometimes warranted in patients with Paget's disease and bony deformities, pathologic fractures, nerve compression, or degenerative arthritis. Orthopedic procedures such as total joint replacement and osteotomies are associated with a reduced risk of intraoperative bleeding or other complications if patients are treated medically (e.g., with calcitonin or other bisphosphonates) to reduce the disease activity and vascularity for at least 6 weeks before the procedure.

## OSTEOPOROSIS INDUCED BY OTHER MEDICATIONS

Aromatase inhibitors in women undergoing breast cancer treatment are associated with bone loss. Post-menopausal women maintain a low level of circulating estrogen because of aromatization of androgens to estrogen in tissues such as fat and muscle by the cytochrome P-450 enzyme. Inhibition of this enzyme is now used in post-menopausal women with breast cancer. There are two classes of aromatase inhibitors: nonsteroidal reversible inhibitors (anastrozole and letrozole) and steroidal reversible inhibitors (exemestane). These agents prevent the conversion of androgen to estrogen, resulting in low serum estrogen levels and increased bone remodeling. In clinical trials of aromatase inhibitors compared with either tamoxifen or placebo, fracture rates ranged from 3% to 7%.[165] In a 2-year study, significantly higher markers of bone turnover and nearly twice the lumbar spine bone loss and fracture rates were observed with anastrozole compared with tamoxifen. Although the data are just beginning to be collected regarding skeletal health in women treated for breast cancer with aromatase inhibitors, it is important to obtain a history of clinical risk factors for osteoporosis and a BMD measurement of the hip and spine. Preventive treatment should be initiated in women with normal or low bone mass and no history of fractures. Treatment of women with low bone mass (a

T-score ≤–2) should be initiated with potent anti-resorptive agents, and BMD should be monitored at least every 2 years. Recent studies with zoledronic acid and denosumab have been reported to be quite effective in this patient population.[166,167] If a woman continues to lose bone mass while taking aromatase inhibitors despite compliance with potent anti-resorptive agents, and if the patient has not been treated with radiation to the skeleton as part of the breast cancer protocol, rhPTH 1-34 treatment can be used to build up bone mass.

Gonadotropin-releasing hormone antagonists are used to treat women with endometriosis and men with prostate cancer. These compounds induce bone loss by lowering estrogen levels, resulting in accelerated bone turnover. In a study of more than 50,000 men with prostate cancer treated with androgen-deprivation therapy consisting of either gonadotropin-releasing hormone agonists or orchiectomy, an increased risk of fracture or hospitalization due to fracture was found. Although the overall risk of fracture associated with androgen-deprivation therapy was only modestly increased overall, the risk of fracture was significantly associated with the number of doses of gonadotropin-releasing hormone agonists.

Other studies have reported that androgen-deprivation therapy increases bone loss at all sites, with a 2% to 8% annual loss in the lumbar spine and a 2% to 6% loss in the hip after 1 year.[168] Given the high incidence of prostate cancer and the increasing use of this treatment, assessment of bone mass and the prevention of additional bone mass loss are probably appropriate. Oncologists currently recommend that BMD be measured at the time of initiation of androgen-deprivation therapy and that clinical risk factors for osteoporosis be reviewed, including the history of fracture after age 30 years, the family history of hip fracture, smoking history, use of glucocorticoids, low testosterone level, and rheumatoid arthritis. If the patient has a low BMD (T-score <–2.5) or a T-score between –1 and –2.5 and other risk factors, treatment with calcium and vitamin D supplementation and a bisphosphonate (zoledronic acid, alendronate, risedronate, or denosumab) should be initiated. BMD of the lumbar spine and hip should be measured at least once a year while patients receive androgen-deprivation maintenance therapy.[169-172]

CHAPTER 102

# Proliferative Bone Diseases

Reuven Mader

**KEY POINTS**

- Diffuse idiopathic skeletal hyperostosis (DISH) is usually defined by the presence of large flowing osteophytes connecting at least four vertebrae, typically in the thoracic spine. However, the disease often involves the cervical and lumbar spine and peripheral joints, especially entheses.
- The cause of DISH is unclear, but it is associated with a variety of metabolic abnormalities, many of which are also seen in type 2 diabetes.
- Treatment of spinal DISH is mostly symptomatic. Patients with DISH are at increased risk for heterotopic bone formation after joint surgery.
- DISH may be associated with increased cardiovascular risk factors. Growth factors are implicated as the common cause of most, if not all, cases of hypertrophic osteoarthropathy (HOA).
- HOA usually responds dramatically to effective treatment of the primary disease such as surgical resection of a lung carcinoma.
- Synovitis, Acne, Pustulosis, Hyperostosis, and Osteitis (SAPHO) syndrome is a chronic inflammatory disorder, often relapsing, of unknown cause. It most commonly affects the anterior chest wall.
- The cause of SAPHO syndrome is unknown, but an infectious etiology has been proposed on the basis of isolation of *Propionibacterium acnes* from sternal osteosclerotic lesions.
- NSAIDs are usually the first line of treatment in SAPHO and may improve symptoms. Additional therapy with other modalities is often required.

Proliferative bone diseases encompass a variety of conditions characterized by exuberant bone and entheseal ossifications and calcifications. New bone formation is the main feature in diffuse idiopathic skeletal hyperostosis (DISH) and hypertrophic osteoarthropathy (HOA) and is a common finding in osteoarthritis. New bone formation may also accompany some spondyloarthropathies such as ankylosing spondylitis, psoriatic arthritis, and sternoclavicular syndrome, also known as SAPHO (synovitis, acne, pustulosis, hyperostosis, and osteomyelitis). New bone formation has also been described in endocrine diseases such as thyroid disorders, acromegaly, and hypoparathyroidism (Table 102-1).[1-3] Osteoarthritis, spondyloarthropathies, and endocrine disorders are discussed elsewhere in this book.

## DIFFUSE IDIOPATHIC SKELETAL HYPEROSTOSIS

DISH is a condition characterized by calcification and ossification of soft tissues, mainly ligaments and entheses. This condition was described by Forestier and Rotes-Querol in 1950[4] and was termed *senile ankylosing hyperostosis*. It has a marked predilection for the axial skeleton, particularly the thoracic spine. Recognition that the condition is not limited to the spine and may involve peripheral joints led researchers to coin the name *DISH*, a term now widely used.[5]

DISH is characterized by the production of coarse, flowing osteophytes involving, in particular, the right side of the thoracic spine with preservation of the intervertebral disk space, as well as by ossification of the anterior longitudinal ligament. Calcification and ossification of the posterior longitudinal ligament seem to be additional skeletal manifestations of DISH. Other entheseal regions may be affected, such as the peripatellar ligaments, Achilles tendon insertion, plantar fascia, olecranon, and others.[6-8]

Diagnosis is usually based on the definition suggested by Resnick and Niwayama.[5] This radiographic approach requires the presence of flowing, coarse osteophytes on the right side of the thoracic spine, connecting at least four contiguous vertebrae, or ossification of the anterior longitudinal ligament, preserved intervertebral disk height in the involved segment, and the absence of apophyseal joint ankylosis and sacroiliac joint involvement (Table 102-2).[8] Another set of criteria, for epidemiologic purposes, was suggested by Utsinger.[7] These criteria also consider peripheral enthesopathies. With these criteria, a definite diagnosis of DISH is established by criteria similar to those suggested by Resnick and Niwayama. A probable diagnosis of DISH is possible, however, with continuous ossification or calcification, or both, of the anterolateral aspect of at least two contiguous vertebral bodies and bilateral well-corticated enthesopathies in the heel, olecranon, and patella. It has also been suggested that peripheral enthesopathies might represent early DISH, which may evolve, over time, to its full radiologic appearance.

### Epidemiology

DISH is more common in men than in women. In a series of 75 spines studied at autopsy, 28% had DISH.[9] The reported prevalence of DISH varies according to age, ethnic origin, geographic location, and clinical setting (i.e., hospital based vs. population based). In a study of a North

American metropolitan hospital population, the prevalence in men and women older than 50 years was reported to be 25% and 15%, respectively, and the prevalence in men and women older than 70 years was 35% and 26%, respectively.[10] Similar figures were reported for patients from Budapest.[11] Higher figures were reported for Jews living in Jerusalem, reaching a prevalence of 46% for men older than 80 years.[12] A much lower prevalence was reported from Korea, reaching only 9% in the older age group.[13] Native Africans in South Africa had a prevalence of 13.6% in patients older than 70 years with no difference between men and women.[14] In population-based, as opposed to hospital-based, studies, the reported prevalence was slightly greater than 10% in patients older than 70 years.[15] Mild DISH was found in human remains dating back 4000 years. In human remains from the sixth to eighth centuries, the prevalence of DISH was higher in men than in women, reaching 3.7%. Although these studies were performed on different and relatively young populations, the prevalence of DISH may be increasing.[16,17]

## Etiology and Pathogenesis

The cause and pathogenesis of DISH are unknown. Several genetic, metabolic, and constitutional factors, as well as other bone formation–promoting peptides, were reported to be associated with this condition. They all might contribute to bone and entheseal new bone formation.

### Genetic Factors

Genetic factors might play a role in the pathogenesis of DISH. It is known that the prevalence of canine DISH in the Boxer breed is about 40%, whereas the overall prevalence of DISH in dogs is 3.8%, suggesting a genetic basis for the risk of developing canine DISH.[18] Familial clustering of DISH or families with early presentation of DISH suggest a genetic background for this disorder in humans.[19,20] Ossification of the posterior longitudinal ligament is closely related to DISH, and the two conditions can coexist. *COL6A1*, which is the candidate gene for ossification of the posterior longitudinal ligament, was reported to be significantly associated with DISH in Japanese patients but not in Czech patients.[21,22] Although the role played by *COL6A1* has not been fully elucidated, it might be involved in ectopic bone formation in ossification of the posterior longitudinal ligament (OPLL), as well as in DISH. This finding would suggest that other factors might play an important role in the genetic predisposition for the development of DISH.

### Metabolic Factors

DISH has been linked to metabolic and constitutional factors such as obesity, a high waist circumference ratio, hypertension, type 2 diabetes mellitus (DM), hyperinsulinemia, dyslipidemia, elevated growth promoting peptides, hyperuricemia, and use of retinoids (Table 102-3).[23-31]

The association of DISH with excess body weight has been well known since the early descriptions by Forestier and other investigators.[9,32] This association was confirmed in a study in which patients with DISH were compared with healthy persons and patients with spondylosis.[33] The association of DISH with type 2 DM has been reported in several studies.[28,30,31] It has been assumed that the higher serum insulin levels in type 2 DM may contribute to the formation of DISH. No studies have been performed to address the issue of type 1 DM or the effect of exogenous insulin administration on new bone formation. However, in a recent study, the prevalence of DISH was no higher in diabetic patients than in nondiabetic subjects, suggesting re-evaluation of diabetes as a risk factor for the development of DISH.[34] More often, DISH was reported to be associated with more complex metabolic and endocrine derangements, with or without overt type 2 DM, comprising glucose intolerance, hyperinsulinemia, dyslipidemia, hyperuricemia, and elevated levels of growth hormone and insulin-like growth factor (IGF)-I.[24,27,30] Because of these metabolic abnormalities, patients with DISH have a higher likelihood of being

affected by metabolic syndrome and are subjected to a higher coronary artery disease risk.[35]

Hyperinsulinemia has a profound effect on ligaments and entheses, which is independent of age and obesity. The differentiation of mesenchymal cells in ligaments into chondrocytes and the subsequent endochondral ossification is promoted by insulin.[28,36] The enthesis provides the growth plate for tendons and ligaments in children and persists into adulthood. This particular structure is composed of collagen fibers, fibroblasts, chondrocytes, and calcified matrix, which is probably a target for the ossification process promoted by insulin.[23]

### Other Bone Formation–Promoting Pathways

Bone morphogenetic protein (BMP)-2 is a potent osteogenic factor that promotes differentiation of mesenchymal stem cells into fibroblasts and chondroblasts. It stimulates cell proliferation, alkaline phosphatase (ALP) activity, and collagen synthesis.[37,38] Its ability to promote mineralization is inhibited by matrix Gla protein, which is highly expressed in bone and cartilage. Matrix Gla protein deficiency or its altered carboxylation may cause a high level of BMP-2 activity that leads to hyperostosis.[31,39] Another possible explanation is the upregulation of BMP-2 and BMP-4 messenger RNA expression after tensile stress on ligaments from patients with OPLL.[40]

The enthesis may also be under the influence of other growth-promoting peptides. Elevated growth hormone levels have been reported in DISH. Growth hormone is capable of inducing osteoblast cell proliferation and may promote local production of IGF-I, which mediates the action of growth hormone and can stimulate ALP activity in osteoblasts.[24,31,41,42] ALP promotes the calcification process during bone formation and is considered a good indicator for the maturation stages of osteoblasts.[43] It has not yet been determined why the new bone formation is localized mainly at the ligamentous and entheseal sites. In male patients with DISH, growth hormone serum levels were not elevated compared with patients with OA, but they were much higher in the synovial fluid.[24,43] In the spine, vertebral blood supply could be a factor in the onset or progression of DISH.[44] Intraerythrocyte growth hormone levels may exceed serum growth hormone levels and could be transported to the vertebral site.[45]

The expression of various genes involved in cell division and growth is regulated by nuclear factor-κB (NF-κB), which is capable of regulating the differentiation of multipotential cells. It has been shown that activation of environmental factors such as platelet-derived growth factor (PDGF)-BB and transforming growth factor (TGF)-β1 in ligament cells stimulates the activation of NF-κB, which influences the osteoblastic differentiation of mesenchymal cells. This event is accompanied by elevation of ALP activity in cells of patients with DISH and serves as an indicator of maturation stages of the osteoblast.[46] Inflammatory cytokines such as PDGF-BB, TGF-β1, and others may be related to the onset of non–insulin-dependent DM and may be the link between this condition and the occurrence of DISH.[47,48]

The Wnt–β-catenin pathway may induce bone formation. Wnt signaling can be inhibited by the endogenous secreted protein dickkopf-related protein 1 (DKK1; also known as dickkopf-1). Low DKK1 levels and thus reduced inhibition of the Wnt pathway might have a role in the development of extensive bony spinal bridges in a subset of patients with DISH.[49,50,51] Vitamin A and its derivatives have been implicated in the pathogenesis of DISH because of their ability to promote new bone formation. Levels of vitamin A were reported to be higher in patients with DISH compared with control subjects, and some reports showed DISH-like manifestations in young patients treated with vitamin A or its derivatives.[25,52] The role of vitamin A in the pathogenesis and clinical manifestations in DISH is still controversial.[53] Larger prospective studies are necessary to elucidate the role played by this vitamin in the pathogenesis of DISH.

Prostaglandin $I_2$ ($PGI_2$) is a potent inhibitor of bone resorption, and endothelin-1 might regulate ectopic calcification of the vasculature but may also regulate the proliferation of osteoblasts and osteoclasts. In vitro studies have suggested that endothelin-1 and $PGI_2$ might play roles in the pathogenesis of DISH by induction, through various mechanisms, of ALP activity and osteogenic differentiation in spinal ligament cells.[54-56]

There are no convincing explanations for the predilection of the hyperostotic process to affect the anterolateral aspect of the thoracic spine. The limited range of motion of the thoracic spine has been cited as a possible cause for the predilection to this site. This assumption cannot explain the involvement of the extremely mobile cervical spine or the lumbar spine, however. The less frequent involvement of the left side of the thoracic spine was ascribed to the pulsation of the aorta. This assumption was based on a few reports that described left-sided bridging osteophytes in cases with a right-sided aorta, suggesting that the aortic pulsations interfere with the production of the osteophytes.[57] Calcifications, ossification, and subsequent stiffening of ligaments and joint capsules have important pathogenetic implications. It has recently been shown that patients with DISH have a significantly higher risk of developing aortic valve sclerosis.[58] Whether this finding might share common pathogenetic mechanisms or only reflects usual risk factors has yet to be determined (Figure 102-1).

Osteoarthritis may have pathogenetic features in common with the peripheral joint manifestations of DISH. It was suggested that in the small non–weight-bearing joints in osteoarthritis, the process is caused by an increased intra-articular pressure and the subsequent development of "crash" forces.[59] This development was attributed to thickening of the collateral ligaments of these joints that enforce a constraint movement, not to primary damage to the cartilage. It seems reasonable that the joints affected by DISH may develop the same "crash" forces operating in small osteoarthritis joints as a result of this mechanism. This mechanism might explain the involvement of "atypical" joints that are not commonly affected by osteoarthritis and the hypertrophic osteoarthritic changes in the commonly affected joints.

## Clinical Manifestations

The lack of specific symptoms and signs of DISH, as well as the radiographic diagnostic criteria, have raised doubts

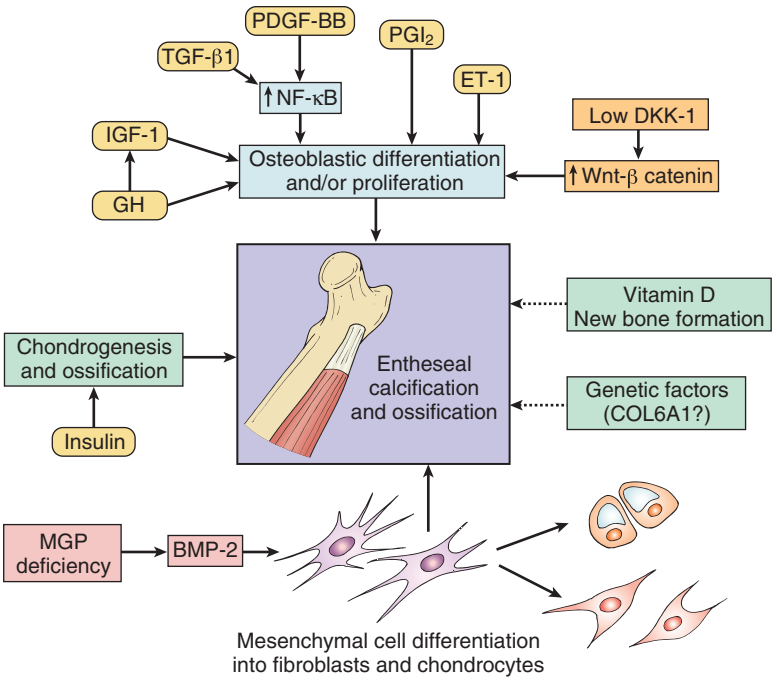

**Figure 102-1** Suggested factors that promote entheseal calcification and ossification in diffuse idiopathic skeletal hyperostosis (DISH). Growth hormone (GH) promotes osteoblastic differentiation and/or proliferation either directly or indirectly by promoting insulin-like growth factor-1 (IGF-1) production. Nuclear factor-κB (NF-κB) activity is stimulated by platelet-derived growth factor-BB (PDGF-BB) and transforming growth factor-1 (TGF-1) and promotes soft tissue ossification. Endothelin-1 (ET-1) and prostaglandin $I_2$ ($PGI_2$) may promote osteoblastic differentiation. Low Dickkopf-related protein-1 (DKK-1) levels enhance the activity of the Wnt-β catenin pathway, which induces osteoblastic differentiation and/or proliferation. Matrix Gla protein (MGP) deficiency increases bone morphogenic protein-2 (BMP-2) activity, leading to the differentiation of mesenchymal cells into chondrocytes and fibroblasts, which may calcify. Insulin induces chondrogenesis and ossification. *(From Mader R, Verlaan JJ, Buskila D: Diffuse idiopathic skeletal hyperostosis: clinical manifestations and pathogenic mechanisms.* Nat Rev Rheumatol *9:741–750, 2013.)*

about DISH as a separate entity.[60] Although the process may be asymptomatic, it has been reported to be associated with morning stiffness, dorsolumbar pain, and reduced range of motion in some patients.[7,8] Patients with DISH may have extremity pain involving peripheral large and small joints and peripheral entheses such as the heel, Achilles tendon, shoulder, patella, and olecranon.

## Spinal Involvement

Pain in the axial skeleton may involve all three segments of the spine and the costosternal and sternoclavicular joints. The level of pain and disability is significantly higher compared with healthy subjects but is not different from patients with spondylosis.[33] In some studies, up to two thirds of the patients with DISH experience morning stiffness and spinal pain, and nearly half have a reduced range of motion.[7,61] Reports of pain referable to the thoracic spine are common and are accompanied by a reduced chest expansion. However, other studies suggested that spinal DISH is not associated with increased pain, and at times patients reported less pain compared with patients who did not have DISH.[62,63]

Although similar in some aspects to osteoarthritis of the spine, DISH is a distinct clinical entity with different characteristics.[64] Classically, the portions of the spine that are involved in osteoarthritis are the lower portions of the cervical spine and the lumbar spine. Thoracic spine involvement is uncommon in osteoarthritis or occurs in late stages of the disease, as opposed to the common involvement of the thoracic spine in DISH. Thoracic spine involvement in DISH is characterized by preserved intervertebral height, whereas in spinal osteoarthritis, reduced intervertebral disk height is common. These differences in the radiologic appearance and anatomic spinal distribution probably have to do with the different pathogenetic mechanisms described earlier. It is presumed that the primary target for the osteoarthritic process is the cartilage represented in the spine by the intervertebral disks and the cartilage of the facet joints.

The wear-and-tear forces operating in the extremely mobile lower cervical and lumbar portions of the spine might explain the frequent involvement of these segments in osteoarthritis, whereas the thoracic spine is the least mobile of the spinal segments. The main targets of the disease in DISH are the spinal ligaments and entheses (Figure 102-2).[5,65] These abnormalities are not limited to the thoracic spine and may involve the lumbar spine and the cervical spine (Figure 102-3). In the lumbar spine, the large bridging osteophytes are not uniformly one-sided.[66] These sites of ossification and subsequent production of large osteophytes may result in spinal stenosis.[67] Severe complications may develop, especially when the cervical spine is affected; these complications include dysphagia, hoarseness, stridor, OPLL, myelopathy, aspiration pneumonia, sleep apnea, atlantoaxial complications, thoracic outlet syndrome, esophageal obstruction, endoscopic and intubation difficulties, and fractures (Table 102-4).[68] The high

prevalence of coexisting intervertebral disk damage in young patients with DISH suggests an important role for DISH in the pathogenesis of spondylosis in this group of patients.[69] At times, patients with DISH may assume the typical postural abnormalities of advanced ankylosing spondylitis such as accentuated kyphosis and reduced mobility

of the spine. These two entities, although they may coexist, can usually be distinguished by the different age of onset, clinical presentation, radiographic appearance of the spine and sacroiliac joints, and *HLA-B27* associations.[70,71]

## Extraspinal Involvement

Clinical manifestations similar or identical to those of osteoarthritis are prominent features of DISH in the peripheral joints. The peripheral joints affected by DISH have features that distinguish them from primary osteoarthritis, however. One is the more frequent involvement of joints that are not usually affected in osteoarthritis such as the metacarpophalangeal joints, elbows, and shoulders (Figure 102-4).[61,72-74] Other features are a more severe hypertrophic disease that may result in a reduced range of motion in the affected joints and calcified and/or ossified prominent enthesopathies.[74-76]

As described previously, the primary event in DISH is thickening, calcification, or ossification of ligaments and entheses. In particular, enthesopathy affecting the peripheral joints has been described.[77] The radiographic appearance of peripatellar, cruciate ligament insertion, and pericapsular osseous enthesopathies are some examples of the contribution of DISH to stiffening of the soft tissues surrounding a joint (Figure 102-5).[78] Entheseal ossification at various sites other than joints such as the heel, ribs, and pelvis is a common finding in DISH. The clinical implications of the peripheral involvement is not clear and is controversial. However, the enthesopathies may become symptomatic, exhibiting pain and swelling in the affected region. A high probability for the presence of spinal DISH was noted for ossification of the iliolumbar and sacrotuberous ligaments and with bony overgrowth of the inferior acetabular rim.[77,79] A higher level of soft tissue tenderness and lower functional status have been reported recently in patients with DISH compared with patients who do not have DISH.[80]

Patients with DISH often have higher body weight and body mass index, waist circumference, and systolic blood pressure.[33] These factors and the metabolic abnormalities described earlier put patients at an increased risk for cardiovascular diseases.[30,81,82] The diagnosis of DISH should be suspected in patients with osteoarthritis in atypical locations (e.g., the elbow), in patients with hypertrophic osteoarthritis, and in patients with large enthesopathies and entrapment neuropathies of uncertain origin. This is particularly true for patients with the associated diseases and metabolic abnormalities previously discussed. It has been shown that chest radiographs may serve as a screening tool for the diagnosis of DISH with a sensitivity of 77% and a specificity of 97%.[83]

**Figure 102-4** Severe hypertrophic osteoarthritis of the proximal and distal interphalangeal joints. Of particular interest is the involvement of the metacarpophalangeal joints with enlarged metacarpal heads, osteophytes, joint space narrowing, and subchondral sclerosis.

### Fracture Risk and Heterotropic Ossification

The sites of ossification and the subsequent production of large osteophytes may result in spinal stenosis[67] and spinal stiffening. Under these circumstances, force cannot be dissipated and the spine behaves like a long bone with an increased risk of fracture.[84] These fractures may be unrecognized, unstable, and associated with treatment delays and permanent neurologic deficits.[85]

The tendency for new bone formation puts the patient at risk for the development of heterotopic ossification after joint surgery[86] and may jeopardize the outcome. Although it is not clear what causes these ossifications, the use of irradiations or prophylactic NSAID treatment has been suggested for the patients at risk.

## Treatment

Treatment of DISH should address several issues. Treatment is expected to alleviate pain and stiffness; prevent, retard, or arrest progression; correct the associated metabolic disorders; and prevent spontaneous or induced complications (Table 102-5).

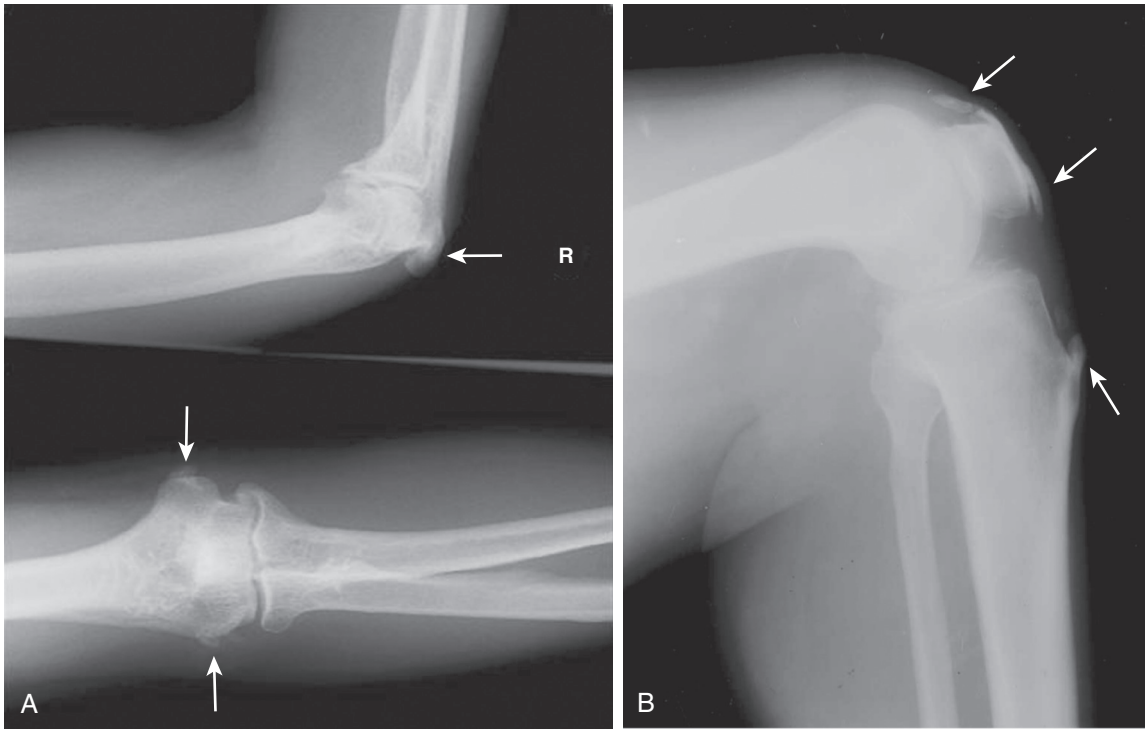

**Figure 102-5** **A** and **B,** Ossified enthesopathies in the peripatellar, olecranon, and humeral epicondyles *(arrows)*.

| Seek a better understanding of the pathogenetic basis for the disease |
| Offer a disease-modifying therapeutic approach |

Specific therapeutic interventions in DISH have not been systematically explored, which is probably related to the inclusion of DISH in the spectrum of osteoarthritis and the assumption that the same therapeutic interventions for osteoarthritis are suitable for DISH. More recently it was suggested that serum levels of growth hormone and IGF-I might be a useful surrogate marker for assessing DISH progression and remission.[38] It was estimated that a period of at least 10 years is necessary for the pathologic process to evolve completely.[87] This notion has been recently corroborated by a computed tomography (CT) study[88] and implies that a long observation period is necessary to show that a therapeutic intervention prevents the development of the disease, arrests its progression, or, it is hoped, reverses the pathologic changes.

Few reports have been published about remedies to alleviate the symptoms of the disease, but some investigators have reported on the beneficial effects of light exercise, heat, analgesics, and NSAIDs.[89] Exercise therapy failed to show a significant improvement in the spinal range of motion except for lumbosacral flexion.[90] More recently, the use of locally acting NSAIDs for the treatment of osteoarthritis was shown to be as effective as the same product by oral route, suggesting that locally acting NSAIDs also might be successfully used for the symptomatic relief of pain and stiffness that may be present in the peripheral joints of patients with DISH.[91] Treatment of symptomatic enthesopathies might be necessary to alleviate local pain and swelling; this treatment can be achieved through use of local soft applications such as insoles for plantar spurs or protective bandages at other sites. Infiltration of a local anesthetic with long-acting corticosteroids may offer at least temporary relief in persons with severe symptoms. When multiple sites are involved, the same therapeutic modalities mentioned for osteoarthritis may be used.

It seems appropriate to screen patients with DISH for known cardiovascular risk factors and to treat them when appropriate. General measures such as weight reduction, adequate physical activity, and a diet low in saturated fat and carbohydrates all might be important in preventing or arresting the progression of DISH. Some of these factors may have pathogenetic implications and may become therapeutic targets. On the basis of present understanding, therapeutic interventions should aim at a reduction of insulin secretion and insulin resistance. In patients with non–insulin-dependent DM, the use of biguanides, which decrease insulin resistance, may offer an advantage compared with the use of sulfonylureas, which increase insulin secretion. When coexisting hypertension is treated, medications that might improve insulin resistance such as angiotensin-converting enzyme inhibitors, calcium channel blockers, and α-blockers are preferred over medications that may worsen insulin resistance, such as thiazide diuretics and β-blockers.[92] Some growth factors that might have a role in the development of DISH such as NF-κB, PDGF-BB, TGF-β1, growth hormone, and IGF-I may become targets for specific therapeutic interventions.

In some patients, several complications can be avoided if they are taken into consideration. Aspiration pneumonia can be partially avoided if instructions in proper deglutition and preservation of an upright position after meals are carefully explained to the patient. Physicians familiar with DISH can avoid or minimize damage to the cervical spine or to soft tissues in patients who might need certain diagnostic or therapeutic interventions such as upper gastrointestinal endoscopy or endotracheal intubation. It is reasonable to adopt common measures to prevent falls and trauma, especially in elderly patients. Heterotopic ossification after orthopedic surgeries, in particular hip arthroplasty, is common in patients with DISH. Several therapeutic interventions aimed at abolishing heterotopic ossification, such as administration of NSAIDs, anti–vitamin K, and irradiation, have been reported with variable success.[93,94] Patients at high risk of developing this complication, such as patients with DISH, should be considered candidates for one of these regimens. Therapeutic options are summarized in Figure 102-6.[95] Many tasks lay ahead to better define this disorder, understand the pathogenesis, and delineate effective interventions (Table 102-6).

## HYPERTROPHIC OSTEOARTHROPATHY

HOA is a well-known entity characterized by skin and bone proliferation and large joint effusions. The hallmark and main visual manifestation is a bulbous deformity of the distal end of the digits, also known as *clubbing* or *drumsticks*. Periostosis is a progressive process with predilection for the tubular bones, principally the tibia and fibula. Periostosis is bilateral, symmetric, and spares the medullary cavity, axial skeleton, and skull. The prevalence of the condition is unknown, but it was found in skeletal human remains from thousands of years ago.[96] It may be primary or secondary.

## Etiology

### Primary Hypertrophic Osteoarthropathy

Primary HOA is an autosomal dominant disorder characterized by periostosis, clubbing, thickening of the skin of the face and scalp, seborrhea, and hyperhidrosis. It is also termed *pachydermoperiostosis*. There is a male predominance, with a male-to-female ratio of 9 : 1; one peak of presentation occurs in the first year of life and the other in adolescence.[97] A mutation in the *HPGD* gene, which encodes the enzymes responsible for prostaglandin metabolism, results in primary HOA.[98]

### Secondary Hypertrophic Osteoarthropathy

Secondary forms of HOA manifest as isolated clubbing or with the full spectrum of the disease. Clubbing may be unilateral or bilateral and has been reported to occur in a variety of diseases, including pulmonary (most commonly cancers), cardiac, gastrointestinal, neurologic, infectious, vascular, and other diseases (Table 102-7).[99-105]

## Pathogenesis

HOA is characterized by excessive collagen deposition, endothelial hyperplasia, edema, and new bone formation mainly involving the distal extremity and eventually progressing proximally. Various hypotheses have been generated in an attempt to explain the development of HOA. Most patients with secondary HOA have severe lung or cyanotic heart diseases. It was suggested that megakaryocytes are fragmented into platelets during their passage in

the lung capillaries. In severe lung diseases or right-to-left shunts, however, megakaryocytes or platelet aggregates bypass the pulmonary capillary bed and lodge in the peripheral vasculature of the digits.

A study showed that locally released growth factors such as vascular endothelial growth factor (VEGF) and PDGF were markedly increased in tissue samples obtained from digits of patients with HOA.[106] It is feasible that these substances might be responsible for the distal overgrowth of collagen and bone. VEGF was found to be produced by a lung tumor in a patient with HOA. In this case, serum levels of VEGF were high, and resection of the tumor reversed the digital clubbing and reduced the serum VEGF levels.[107] Activation of platelets and endothelial cells was supported by an increase in circulating von Willebrand factor antigen.[108] Other growth factors have been associated with digital clubbing, including hepatocyte growth factor, which was found to be increased in the serum of patients with lung cancer and HOA compared with patients who had lung cancer but did not have HOA.[109]

## Clinical Manifestations

HOA is often asymptomatic, and sometimes it is the patient who notes changes in the shape of his or her fingers. Symptomatic patients report a deep-seated pain in the lower extremity and over the long tubular bones, which is exacerbated by palpation. Large joint effusions are common, and the synovial fluid is thick with few white blood cells.[110] Skin hypertrophy may be confined to the nail beds or involve the face or larger areas overlying the tubular bones or joints.

The most common and apparent clinical manifestation is digital clubbing. The bulbous deformity of the fingertips is accompanied by a convex nail (watch-crystal nail). The skin around the nail bed becomes shiny and thin, with disappearance of the creases (Figure 102-7). Palpation of the base of the nail bed yields the sensation of a "floating" nail within the soft tissue. Cases of advanced clubbing can be identified easily. Several methods have been developed to diagnose early phases of the condition. Among those techniques, the digital index and the phalangeal depth ratio have been most widely used.[111,112] The digital index measures the ratio between the circumference at the level of the nail bed and the circumference at the distal interphalangeal joint of the 10 fingers. A sum of ratios greater than 10 suggests clubbing. The phalangeal depth ratio measures the ratio between the depth of the distal phalanx and the depth of the distal interphalangeal joint of the index finger. A ratio greater than 1 is considered abnormal.

No specific laboratory tests are available to diagnose HOA. Radiographs of the fingers and toes may show acroosteolysis, and periostitis manifests by cortical thickening of long bones. The process may involve few or multiple sites and can be regular or irregular in appearance. Characteristically, there is no reduction in joint space or erosions. Radioisotope bone scanning can be useful for diagnosis and for evaluating the extent of the process. Increased uptake can be seen in the cortex of long bones, sometimes in the form of splints (Figure 102-8).

## Treatment

Asymptomatic persons do not need to be treated. NSAIDs are sometimes useful in symptomatic patients. Case reports have suggested that significant pain relief was observed after treatment with octreotide or bisphosphonates.[113,114] In secondary cases of HOA, all features and symptoms promptly regress with successful treatment of the primary disease, such as correction of a heart malformation, removal of tumors, and therapy of infective endocarditis or inflammatory bowel disease. The role played by VEGF in the pathogenesis of HOA suggests that treatment with VEGF inhibitors might improve the symptoms of this condition.[115]

## SAPHO SYNDROME

SAPHO syndrome is a chronic inflammatory disorder, often relapsing, of unknown cause. The term SAPHO was coined to include several associated clinical manifestations: synovitis, acne, pustulosis, hyperostosis, and osteitis.[116] The most common sites of bone involvement are in the anterior chest wall—mainly the clavicles, sternum, and sternoclavicular joint.[117] The syndrome has been associated with a variety of skin lesions such as acne conglobata, acne fulminans, palmoplantar pustulosis, and psoriasis. The condition is uncommon with an estimated prevalence of 1 in 10,000, but the exact prevalence is difficult to establish in the absence of validated diagnostic or classification criteria. Furthermore, it is presumed that the prevalence of SAPHO syndrome is underestimated, particularly in patients with mild or absent skin manifestations.[118]

### Etiology and Pathogenesis

The cause of SAPHO syndrome is unknown. An infectious cause has been proposed on the basis of the isolation of *Propionibacterium acnes*, a slowly growing anaerobic microorganism often found in acne, from sternal osteosclerotic lesions.[119] It has been postulated that *P. acnes* might act directly, inducing bony erosions through chronic indolent inflammation. It has also been suggested that *P. acnes* may trigger complement activation and promote production of IL-1, IL-8, and TNF, which contribute to both humoral and cellular pro-inflammatory responses. An imbalance between pro-inflammatory and anti-inflammatory mediators also has been suggested to contribute to the inflammatory response and the subsequent damage.[120,121]

Genetic susceptibility has not yet been found. Specifically, no associations with *HLA-B27*, other alleles often associated with psoriatic arthritis, or other candidate genes have been identified.[117,122,123]

In patients with SAPHO syndrome, the reported prevalence of common autoantibodies encountered in autoimmune diseases was 22%. The autoantibodies did not show a specific profile but suggest a possible relationship between autoimmunity and SAPHO.[124] It has been suggested that the increased association of SAPHO syndrome with inflammatory bowel disease might link SAPHO to the seronegative spondyloarthropathies, but this view has not yet been confirmed.[117,125]

### Clinical Manifestations and Imaging

SAPHO syndrome is characterized by the combination of skin and osteoarticular manifestations. The skin manifestations include palmoplantar pustulosis, severe acne, suppurative hidradenitis, and at times psoriasis. The skin manifestations can precede or follow the osteoarticular manifestations, at times by many years.[117,126,127]

The osteoarticular features of SAPHO syndrome are hyperostosis, aseptic osteitis that occasionally involves the adjacent joints, and synovitis. The early histologic findings of the bone lesions are similar to those of osteomyelitis with periosteal bone formation. Subsequently the lesions evolve into chronic inflammation with a preponderance of mononuclear infiltrate; it is only in the late phases that prominent marrow fibrosis, sclerosis, and enlarged bone trabeculae ensue.[128]

The most characteristic clinical manifestation is pain in the anterior chest wall as a result of common involvement of the clavicles, sternum, and sternoclavicular joints.[117,127] Other common sites of involvement in the axial skeleton are the vertebral bodies with vertebral sclerosis; hyperostosis; spondylodiskitis; nonmarginal syndesmophytes, at times with anterior bridging; the bone adjacent to the sacroiliac joint; and the pubic symphysis.[125,129] Extraspinal involvement is infrequent but may be observed in the form of osteitis involving the tibia, femur, or mandible and with arthritis involving the knees, hips, ankles, or small joints of the hands and feet.[117,125,130] The diagnosis is highly suspected in cases that feature usually sterile, multifocal, recurrent osteomyelitis, with or without cutaneous lesions; arthritis associated with palmoplantar pustulosis, pustular psoriasis, or severe acne; and osteitis associated with severe acne, palmoplantar pustulosis, or pustular psoriasis.[127]

Laboratory investigations may reveal a moderately elevated erythrocyte sedimentation rate or acute phase reactants such as C-reactive protein, C3, and C4. These findings may reflect the inflammatory nature of the condition but are less reliable than in other inflammatory rheumatic disorders.[117,125]

The diagnosis is usually established with the correlation between the clinical presentation and imaging findings. Bone scintigraphy has sufficient sensitivity to detect the anterior chest wall involvement, demonstrating the characteristic "bull's head" sign.[131] Plain radiographs may detect advanced lesions, but a CT scan enhances the ability to detect these lesions, in particular in flat bones. Radiographic studies of the anterior chest lesions show osteitis in the form of osteosclerosis with a homogeneous fibrillary pattern, hyperostosis in the form of periosteal reaction, and cortical thickening leading to bone hypertrophy. These lesions with eventual erosive arthritis (due to either primary arthritis or extension of the adjacent osteitis) classically involve the sternoclavicular joint and the upper costosternal and manubriosternal junctions. The spine, which is involved in about a third of the patients, presents with a similar radiographic appearance with vertebral sclerosis, hyperostosis, spondylodiscitis, nonmarginal asymmetric syndesmophytes, and at times hyperostosis in the form of osseous bridging along the anterior aspect of the spine.[126] In a recent MRI study, corner vertebral erosions were a consistent finding, frequently with involvement of the vertebral end plates and at times adjacent vertebra.[132] The meaning of these findings has not yet been fully elucidated, and further studies are necessary. Entheseal ossifications, osteitis, osteosclerosis, and periosteal new bone formation have all been reported with variable frequency in long bones.

### Treatment

NSAIDs are usually the first line of treatment and may improve symptoms. However, they often fail to control the disease, and additional therapy with corticosteroids and other modalities is required.[117,133] Several empiric therapeutic approaches have been reported in SAPHO, including NSAIDs, corticosteroids, bisphosphonates, sulfasalazine,

methotrexate, cyclosporine, leflunomide, antibiotics, and anti-tumor necrosis factor (TNF) agents,[133] but have yielded mixed results.[125,133,134] Treatment with antibiotics, usually azithromycin, has been reported to be beneficial in patients with SAPHO syndrome. However, many patients were also treated with other disease-modifying antirheumatic drugs, and the response faded after discontinuation of the antibiotic. It is not clear whether the response to the antibiotic, although transitory, is due to its antibacterial or anti-inflammatory effect.[135] In recent years it has been reported that bisphosphonates, in particular pamidronate, elicit a good or partial response in the majority of patients affected by SAPHO syndrome.[136] It seems that beyond their ability to prevent bone resorption, bisphosphonates are capable of suppressing the production of proinflammatory cytokines such as IL-1, TNF, and IL-6.[137] Treatment with TNF blockers has emerged as an effective therapy in selected cases. The results appear to be less spectacular than in other seronegative spondyloarthropathies and may be hampered by relapse of the skin manifestations.[138,139] Recently, anakinra, an IL-1 receptor antagonist, and other biologic agents have been proposed as possible therapies for this condition.[140,141]

CHAPTER 103

# Osteonecrosis

Christopher Chang • Adam Greenspan • Javier Beltran • M. Eric Gershwin

## KEY POINTS

- Younger patients are affected more often by osteonecrosis than by osteoarthritis, and osteonecrosis has significantly greater long-term morbidity.
- Corticosteroids are the most common cause of nontraumatic osteonecrosis.
- The femoral head is the most common site of osteonecrosis.
- In rare instances, osteonecrosis of the jaw has been associated with bisphosphonate exposure. This phenomenon is more common with repeated intravenous infusions of bisphosphonates.
- Case reports of osteonecrosis of the jaw in association with other medications, such as denosumab, have been reported.
- The final common pathway in the pathogenesis of osteonecrosis is disruption of blood supply to a segment of bone.
- Abnormalities in lipid metabolism, bone homeostasis, regulation of apoptosis, coagulopathies, innate immunity, and oxidative stress may play a role in the pathogenesis of osteonecrosis.
- Epigenetics may alter the predisposition to develop osteonecrosis.
- MRI is currently the optimal test for early diagnosis and identification of the extent of osteonecrosis.
- Nonsurgical treatment of osteonecrosis does not change the natural history of the disease.
- Although surgical treatment of femoral head osteonecrosis has many variations, most symptomatic patients eventually require total hip arthroplasty.
- Knowledge of risk factors and early detection are crucial to the successful management of osteonecrosis.
- Because of the lack of successful treatment options, new modes of management focus on the prevention of osteonecrosis.

Osteonecrosis literally means "bone death" (*ossis* [Latin] = bone; *necrosis* = killing or causing to die). Synonyms include *avascular necrosis*, *ischemic necrosis of bone*, *aseptic necrosis*, and *subchondral avascular necrosis*. Although the term *osteonecrosis dissecans* is sometimes used synonymously with osteonecrosis, strictly speaking, it is a consequence of osteonecrosis involving fragmentation of bone that leads to fracturing or cracking of bone. The concept of bone death was first described by Hippocrates,[1] but the first clinical description of osteonecrosis was a case of sepsis-induced bone death described by Russell in 1794.[2] The first description of the occurrence of bone death in the absence of infection was published almost a century later.[3] The first report of osteonecrosis in a deep sea diver appeared in 1936.[4] The pathogenesis of osteonecrosis is complex, and immune regulation of bone homeostasis may play a significant role, but ultimately, bone death occurs as a result of complete or partial disruption of the delivery of oxygen and/or nutrients to the bone and surrounding tissues. It is likely that multiple molecular mechanisms must be in play simultaneously for osteonecrosis to occur.[5-7]

## EPIDEMIOLOGY

The prevalence of osteonecrosis is unknown, but it is estimated that 10,000 to 20,000 new patients are diagnosed every year in the United States. Osteonecrosis occurs in 15% to 80% of patients with femoral neck fractures.[6] Osteonecrosis is believed to be the cause of 10% of the 500,000 hip replacements performed in the United States each year.[8] Osteonecrosis primarily affects men, with the notable exception of osteonecrosis associated with systemic lupus erythematosus, which has a significant female predominance. Osteonecrosis primarily occurs in the third to fifth decade of life,[9] and consequently, long-term morbidity can be significant because most hip replacements have a finite period of viability.

Recently, osteonecrosis of the jaw (ONJ) has been increasingly reported as a consequence of bisphosphonate use. Other drugs and procedures, including dental implants have been associated with ONJ. In a Spanish study of a population center of 1.1 million, 70 cases of ONJ were identified, with patients in 25% and 75% of these cases receiving bisphosphonates orally and intravenously, respectively.[10]

## ETIOLOGY

Osteonecrosis has been linked to numerous conditions (Table 103-1). The strength of a causal relationship varies greatly, and in some cases only case reports have been published. The most common cause of nontraumatic osteonecrosis is corticosteroid use, which was first described in 1957.[11] Although other adverse effects of corticosteroids are perhaps better known, osteonecrosis of the femoral head is one of the more serious complications. Clearly there exist individual susceptibility differences that are not predictive, and therefore it is important that steroids be prescribed only when indicated and only for the length of time required. As will be discussed, although it is safe for some people to take

**TABLE 103-1** Conditions Associated With Osteonecrosis

| |
|---|
| Dietary, Drug, and Environmental Factors |
| Corticosteroids[190-192] |
| Bisphosphonates[159,193,194] |
| Alcoholism[22,195] |

| Organ transplantation (with or without corticosteroid exposure)[239-244] |
| Radiation exposure[245-250] |
| Regional deep hyperthermia[251] |
| Acute lymphoblastic leukemia[252,253] |

large doses of steroids for long periods, avascular necrosis will develop in other patients who take smaller doses over shorter periods.

In a 1998 study in which the investigators reviewed associations in approximately 3000 cases of nontraumatic osteonecrosis, corticosteroid use was present in 34.7% of cases. Alcohol use was found in 21.7% of cases, and the remainder of the cases were idiopathic. Although the risk of developing osteonecrosis with corticosteroid use is small, because of the severity of the adverse event and the high morbidity associated with it, osteonecrosis is an important complication to consider when prescribing corticosteroids.

Studies have been performed to attempt to determine the duration of use and the dosages of corticosteroids necessary to precipitate osteonecrosis. Because several forms of corticosteroids exist with differing potencies and half-lives, and because dosages and duration of use vary between studies, any conclusions about a "safe" dose of corticosteroids are fraught with potential confounding variables and errors. In a study of 20 patients diagnosed with stage 1 osteonecrosis by MRI, the interval between the use of steroids and diagnosis ranged from 1 to 16 months.[12] The cumulative dose of steroids in this study ranged from 1800 to 15,505 mg (mean, 5928 mg) of prednisolone or the equivalent. In other studies, cumulative doses of steroids associated with osteonecrosis ranged from 480[13] to 4320[14] mg of dexamethasone dose equivalence. In a 2010 article, Powell and colleagues[15] collectively analyzed the available literature to derive maximum safe levels for duration, maximum daily dose, and average daily dose of corticosteroids. The study confirmed that many other confounding variables affect the development of osteonecrosis, making analysis of dose-response risk for an isolated association difficult. Nonetheless, corticosteroid-induced osteonecrosis is dependent on dosage, and the risk is higher with long-acting steroids and with parenteral usage.

Additional host-inherent risk factors also play a role in susceptibility. The incidence of osteonecrosis in a group of patients receiving glucocorticoid replacement therapy for primary or secondary adrenal insufficiency was 2.4%. In a study of patients undergoing renal transplantation, the 26 patients in whom osteonecrosis developed had taken a higher cumulative oral dose of prednisone after 1 and 3 months compared with 28 control patients undergoing renal transplantation in whom osteonecrosis did not develop.[16] A separate study estimated the incidence of osteonecrosis in patients undergoing renal transplant to be 5%.[17] No consistent evidence links the use of topical, inhaled, or nasal corticosteroids to osteonecrosis. The evidence for an association between osteonecrosis and intramuscular or intra-articular corticosteroids is limited to case reports.[18] Parenteral use poses a higher risk because of the rapid absorption and longer half-life of the drugs used. Bisphosphonate-induced osteonecrosis of the jaw is particularly interesting because the intended beneficial use of bisphosphonates with regard to bone diseases instead leads to a serious bone complication itself.[19-21]

Other associations include a link between cigarette smoking and osteonecrosis, with smokers having a threefold higher relative risk for the development of osteonecrosis, independent of all other factors.[22,23] The association between osteonecrosis and alcohol consumption was first described in 1922.[24] A study of patients with idiopathic osteonecrosis revealed that the risk of osteonecrosis increased with increasing daily consumption of alcohol.[23] The subjects were divided into three groups on the basis of their alcohol consumption of less than 400 mL/week, 400 to 1000 mL/week, and greater than 1000 mL/week, and the relative risk of osteonecrosis for these groups, independent of corticosteroid use or smoking, was 3-fold, 10-fold, and 18-fold, respectively. It was also found that liver damage is not necessary for the development of osteonecrosis in patients who

consume alcohol, although elevated liver enzymes may be present.[25] The incidence of osteonecrosis in patients who received treatment for alcoholism was 5.3%. The femoral head was again the most common site (representing 82 of 92 lesions), with the other 10 lesions in the humeral head.[26]

Musculoskeletal conditions can lead to osteonecrosis in children. Legg-Calvé-Perthes disease was first described in children between 3 and 12 years of age in 1910.[27-29] Femoral head osteonecrosis is a feature of this disease and has been linked to trauma,[30,31] congenital hip dislocation,[32] and transient synovitis.[33] Bilateral involvement is common, and associated clinical manifestations include abnormal growth and stature,[34,35] delayed skeletal maturation,[36] disproportionate skeletal growth,[35] congenital anomalies,[37] and abnormal hormone levels.[38,39] Osteonecrosis can develop in children with acute lymphoblastic leukemia as well,[40,41] but this phenomenon may be a result of steroid use. An additional risk factor for patients with acute lymphoblastic leukemia has been found to be high body mass index.[42]

Osteonecrosis has also been associated with metabolic disorders and pregnancy. Diagnosis is often delayed in mothers until months after delivery. Women who experience osteonecrosis during pregnancy tend to have a small body frame and a large weight gain.[43]

Hematologic conditions have been associated with osteonecrosis. The long-term morbidity of osteonecrosis in patients with sickle cell anemia is dismal.[44] Common issues include decreased mobility, abnormal gait, and leg-length discrepancy.[45] Osteonecrosis in patients with hemophilia has been reported, but no statistically reliable causal link has been established.[46-51]

Dysbaric osteonecrosis has been reported in construction workers exposed to high pressure environments, such as the Elbe tunnel, and may have been a feature of the first report of Caisson disease.[52] The prevalence of dysbaric osteonecrosis is 4.2% in divers and 17% in workers exposed to compressed air.[53] Patients with dysbaric osteonecrosis may have more than one lesion; in addition to the femoral head, common sites include the tibia and the humeral head and shaft. The condition is not related to decompression sickness, and although proper decompression procedures can reduce the incidence of "the bends," they do not have any effect on the development of osteonecrosis, which can occur months or years after the last exposure to high-pressure environments.

Osteonecrosis has also been associated with a number of infectious diseases, including severe acute respiratory syndrome (SARS). Many patients who contracted SARS in the early 2000s received treatment with corticosteroids, and osteonecrosis subsequently developed in some of these patients.[54] The incidence of osteonecrosis appears to be higher in this group of patients than in patients with other conditions who were treated with corticosteroids.[55] Chan and colleagues[56] reported that osteonecrosis developed in five children with SARS who were treated with corticosteroids.

## CLINICAL FEATURES

### Osteonecrosis

The primary presenting symptom in osteonecrosis is pain, although many patients may be asymptomatic in the early phases of the disease. In osteonecrosis of the femoral hip, the pain is located in the hip joint but may radiate to the groin, anterior thigh, or knee. The severity of the pain can vary, depending on the size of the infarct and whether the onset of disease is insidious or sudden. When sudden and severe disruption of blood flow occurs in trauma, and when large infarcts occur in the presence of Gaucher's disease, dysbarism, or hemoglobinopathy, pain can be intense and sudden. In other conditions with a more insidious onset, the pain can follow a gradual and slow incremental progression. The pain of osteonecrosis is usually increased with use of the joint, but in individuals with advanced disease, the pain can be persistent at rest. Limitation of range of motion is progressive and is usually a late symptom, except when it results from accompanying pain. The risk of developing osteonecrosis of the contralateral hip when one side is affected ranges from 31% to 55%.

In addition to the femoral head, osteonecrosis can affect other sites such as the humeral head,[57-60] femoral condyles[61-64] and proximal tibiae,[62,65-67] the wrists and ankles,[68] the bones of the hands and feet,[69] the vertebrae,[70-72] the jaw,[73-76] and bony structures of the face.[77] Osteonecrosis of the humeral head is the second most common location; pain is usually present in the shoulder and is associated with reduced range of motion and weakness. Pain in the ankle is the main presenting symptom in nontraumatic osteonecrosis of the talus, and in some cases, the disease has already progressed to Ficat and Arlet stage 3 by the time pain presents.[67] Kienböck's disease involves osteonecrosis of the lunate. Patients present with pain in the radiolunate joint, along with weakness and limitation of motion. Kienböck's disease appears to be related to manual labor. Soccer players have been reported to develop osteonecrosis of the foot,[78] and football players may be prone to the development of osteonecrosis of the hip.[79]

### Staging Osteonecrosis

The Ficat and Arlet method of staging osteonecrosis consists of four stages. Stages 1 and 2 are reversible, whereas stage 3 (subchondral collapse) and stage 4 (joint space narrowing and destruction of cartilage) are irreversible. The Marcus staging system consists of six stages, with the first two reversible and the subsequent four stages irreversible. The modified Steinberg staging system is based on the Marcus system and also consists of six stages. Each stage is further divided into three subclasses on the basis of the extent of femoral head involvement. In subclass A, involvement is less than 25%; in subclass B, 26% to 50% of the femoral head is involved; and in subclass C, greater than 50% of the femoral head is involved.

Table 103-2 shows the Modified Steinberg system for staging osteonecrosis. The Association of Research Circulation Osseous (ARCO) has proposed a modification to the Ficat and Arlet system, adding a stage 0 for patients with negative findings of imaging studies but who are at risk for the development of osteonecrosis. In addition, stages 1 and 3 are further stratified to take into account lesion size, location, and extent of collapse.[80] In 2001 the Japanese Ministry of Health, Labor, and Welfare proposed revising criteria for the diagnosis and staging of osteonecrosis of the femoral head.[81] Diagnostic criteria included (1) collapse of the

**TABLE 103-2** Modified Steinberg Staging Systems for Osteonecrosis

| Stage | Radiographic Appearance | Reversible |
|---|---|---|
| I | Normal radiographs, but abnormal bone scan or MRI | Yes |
| II | Lucent and sclerotic changes | Yes |
| III | Subchondral fracture without flattening | No |
| IV | Subchondral fracture with flattening or segmental depression of the femoral head | No |
| V | Joint space narrowing or acetabular changes | No |
| VI | Advanced degenerative changes | No |

femoral head without joint space narrowing or acetabular abnormality as seen on a plain radiograph, (2) demarcating sclerosis in the femoral head without joint space narrowing or acetabular abnormality, (3) "cold in hot" areas on bone scans, (4) a low-intensity band on T1-weighted MRI, and (5) histologic findings of trabecular and marrow necrosis. If a patient fulfills two of the five criteria, the diagnosis is established. The working group also proposed four types of lesions based on extensiveness and defined stages of disease according to diagnostic imaging.

## Bone Marrow Edema

Bone marrow edema is a common observation in people with osteonecrosis and is frequently accompanied by vascular congestion. Bone marrow edema is not specific for osteonecrosis and may be seen in many musculoskeletal disorders, including osteomyelitis, osteoarthritis, occult intraosseous fracture, stress fracture, osteoporosis, and sickle cell crisis.

A specific syndrome known as *bone marrow edema syndrome* was initially thought to be a precursor to osteonecrosis, but it is now believed to be a separate entity. Bone marrow edema is a transitory, self-limiting condition typically seen in middle-aged men or in women in their third trimester of pregnancy. Patients report pain, limited range of motion, and an abnormal gait. Osteopenia is detected with conventional radiographs, and MRI confirms this diagnosis with a low signal on T1-weighted images and a high signal on T2-weighted images. The three phases of bone marrow edema syndrome include an initial phase lasting about 1 month, followed by a plateau phase lasting 1 or 2 months, and finally a regression phase lasting an additional 4 to 6 months.[82] Subchondral fractures do not occur. Biopsy specimens obtained in the initial phase show diffuse interstitial edema, fragmentation of fatty marrow cells, and increased formation of new bone.[83]

A study of 24 cases of bone marrow edema syndrome of the knee showed that although migrating bone marrow edema occurred in a third of patients at 5-year follow-up, the patients were asymptomatic and MRI signal alterations had resolved. Biopsy specimens of affected bone were obtained using arthroscopic surgery and core decompression, and histologic findings revealed areas of bone marrow edema and vital trabeculae covered by osteoblasts and osteoid seams. None of the cases progressed to osteonecrosis.[84]

## Bisphosphonates, Denosumab, and Osteonecrosis of the Jaw

Bisphosphonate is a class of drug used to treat osteoporosis and diseases in which bone is not formed adequately. Two forms of bisphosphonates are available, and osteonecrosis appears to occur in association with bisphosphonates that contain nitrogen. The mechanism of action of bisphosphonate-induced ONJ appears to parallel that of glucocorticoids, with derangement in lipid metabolism, bone homeostasis, and apoptosis of bone cells all playing a role. It is interesting that the jawbone seems to be the most vulnerable bone in bisphosphonate-induced disease, as opposed to the femoral head in most other associations or causes of osteonecrosis. This phenomenon may be a result of the high bone turnover rate in the jaw or because bisphosphonates exert their action not only on bone but also on many elements of the surrounding tissue, including fibroblasts and blood vessels.

ONJ increasingly has been recognized as a significant disease, and in addition to bisphosphonate use, other causes have been reported in recent years. Many of these findings are from case reports, but epidemiologic studies are beginning to appear in the literature. For example, a case of ONJ was reported in association with the use of raloxifene. Raloxifene is a nonsteroidal benzothiophene that is used as an estrogen receptor modulator to treat osteoporosis in postmenopausal women and to reduce the risk of breast cancer.[85] Denosumab, a monoclonal antibody against receptor activator of nuclear factor-κB ligand (RANKL) that is used in the treatment of osteoporosis, has also been implicated in ONJ. In addition to case reports,[86-88] animal studies also suggest that anti-RANKL interferes with the normal bone resorptive functions of osteoclasts after dental trauma,[89,90] which may play a role in the pathogenesis of ONJ.

German investigators analyzed 1229 cases of ONJ between 2004 and 2012 for risk factors. The indication for bisphosphonate use was primarily cancer, and it was found that ONJ developed earlier in men than in women. Most of the patients (81%) were taking zoledronate at the onset of ONJ.[91]

# PATHOGENESIS

## Anatomic Considerations in Trauma-Related Osteonecrosis

The femoral head is the most common site of osteonecrosis. An understanding of the anatomy of the femoral head may help explain why that is the case.

Three arterial networks supply the femoral head and neck. The extracapsular arterial ring consists of the lateral femoral circumflex artery and the medial femoral circumflex artery, which arise from the profunda femoris. The medial femoral circumflex artery and its branches supply most of the blood to the head and neck of the femur. The lateral femoral artery winds anterolaterally, and the medial femoral artery winds posteromedially around the neck of the femur; they ultimately anastomose with each other at the superolateral aspect of the femoral head. The lateral femoral circumflex artery and the medial femoral circumflex artery further anastomose with the superior and inferior gluteal

branches of the internal iliac artery, providing collateral circulation between the femoral artery and the internal iliac artery. Small vessels known as *retinacular arteries*, which are ascending cervical branches of the extracapsular ring, form an intra-articular ring at the level of the cartilage. Epiphyseal arterial branches arise from this ring and penetrate the head and neck of the femur, including the epiphyses. The artery of the ligament of the head of the femur is a branch of the obturator artery and may be the sole supplier of blood to the proximal fragment of the head.

Some of these anatomic features may render the femoral head particularly vulnerable to ischemia. The retinacular arteries are believed to supply 80% of the femoral epiphysis. Compromise of this critical vascular system may lead to osteonecrosis originating in the anterosuperior aspect of the femoral head, as indicated by angiographic studies in early osteonecrosis in which these arteries are not visualized. A schematic of the blood supply to the femoral head is shown in Figure 103-1.

Histologically, after an infarct, a rim of bony thickening or sclerosis begins to form at the margins of the infarcted area. If the necrotic lesion is within the weight-bearing region of the femoral head, subchondral fractures occur. With repeated microfractures and continued weight bearing, the original fracture cannot heal completely and new fractures appear. The secondary fracture propagates along the junction between subchondral bone and the necrotic segment. As time goes on, the femoral head becomes flattened and eventually collapses. A nonspherical head articulating with the acetabulum produces friction, erosion, and loss of cartilage. The cycle repeats itself, and the structure of the joint deteriorates, leading to degenerative changes and eventual total joint destruction.[92-94]

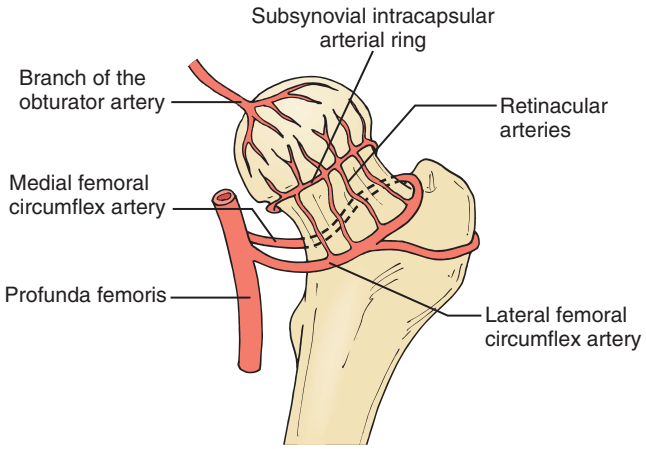

**Figure 103-1** The blood supply of the femoral head.

## Nontraumatic Osteonecrosis

Disruption of the blood supply to the femoral head can occur through a number of different mechanisms. In traumatic osteonecrosis of the femoral head, the cause of this disruption is often viewed as completely mechanical. However, as in the case of nontraumatic osteonecrosis (to be discussed in the following text), an additional component to the disruption may exist that is related to the immunologic and inflammatory changes that occur in damaged bone tissue and surrounding soft tissues.

The immunologic changes occurring in nontraumatic osteonecrosis may help explain why corticosteroids are particularly dangerous to the integrity of the blood supply of the femoral hip. Some investigators have likened osteonecrosis to "coronary disease" of the hip[95,96] and propose that the same mechanisms that cause ischemia of the myocardium may also cause ischemia of the femoral head (Table 103-3).

## Mechanical and Vascular Considerations

In Legg-Calvé-Perthes disease, obstruction to venous drainage elevates intraosseous pressure and consequently increases intra-articular pressures. In a study of patients with Legg-Calvé-Perthes disease, bone scintigraphy using technetium 99m methylene diphosphonate (Tc 99m MDP) was used to measure arterial and venous flow in the diseased hip. Although arterial flow was normal, venous drainage was significantly disrupted.[97] This disturbance was reproduced in a dog model in which injection of silicone was used to obstruct venous flow distal to the hip.[98] Ischemia resulted from the obstruction to venous drainage, leading to a cessation of endochondral ossification in the preosseous epiphyseal cartilage and the physeal plate. Widening of the joint space ensued, followed by revascularization of the epiphysis and deposition of new, immature bone. A weakened or

unstable femoral epiphyseal plate resulted, and the subchondral bone became prone to segmental collapse and fracture.[99]

The pathologic mechanism of dysbaric osteonecrosis is unclear. The most intuitive explanation is that formation of gas bubbles causes arterial occlusion and ischemia. However, the true mechanism may not be quite so simple. Multiple other factors might contribute to the disease, including thromboembolic events such as platelet aggregation, erythrocyte clumping, lipid coalescence, intraosseous vessel compression as a result of extravascular gas bubbles, formation of fibrin thrombi, and narrowing of arterial lumina as a result of myointimal thickening caused by gas bubbles. The interaction between gas and blood can lead to the formation of vessel-occluding substances. All of these events can lead to redistribution of blood flow.

The increased vulnerability of bone to compression disorders has been explained by several factors, including the relative rigidity of bone and its inability to absorb increased gas pressure, inherent poor vascularization, and gas supersaturation of fatty marrow.[100] A sheep model of dysbaric osteonecrosis has been developed. Exposure to compressed air at pressures of 2.6 to 2.9 atmospheres for 24 hours results in extensive bone and marrow necrosis. The authors proposed that the initial event involving elevated intramedullary pressures leads to the formation of nitrogen gas bubbles in the fatty marrow of the long bones. Radiography shows medullary opacities and endosteal thickening. Later, neovascularization of previously ischemic fatty marrow occurs, followed by new bone formation. Osteonecrosis occurs in subchondral cortical bone with marrow fibrosis and osteocyte loss.[101]

Changes in the vasculature through injury or inflammation from other diseases may in turn lead to a compromise in blood flow. Examples include structural damage to arteriolar walls, degeneration of the tunica media, smooth muscle cell necrosis, and disruption of the internal elastic lamina. These changes can lead to eventual hemorrhagic infarction, which was observed in a study of 24 core biopsy specimens from osteonecrotic femoral heads. The changes did not occur in 11 femoral heads affected by osteoarthrosis.[102]

## Osteoimmunology

Although bone marrow is a critical component of the immune system, the bone matrix itself has often been perceived to be merely static scaffolding that functions as a support for the musculoskeletal system. In fact, it is now known that bone matrix is a dynamic tissue that is constantly replacing itself. It is estimated that about 10% of a person's bone is replaced every year. Diseases such as osteopetrosis and osteoporosis are a result of a dysfunction in the balance between bone deposition and bone resorption. The factors that regulate this homeostasis include cells of the bone matrix, immune cells, signaling molecules, cytokines and chemokines, and vitamins and hormones. Some of these regulatory factors may be present on both bone cells and immune cells, often serving different functions, thereby providing a link between the immune system and bone. Osteonecrosis, in fact, may be a result of such an imbalance in bone homeostasis. Immune factors may affect surrounding soft tissue as well, contributing to the development of osteonecrosis. The study of immune regulation of bone in osteonecrosis encompasses many of the previously proposed mechanisms of osteonecrosis, including apoptosis, oxidative stress, and genetic predisposition.

Immune factors involved in bone homeostasis include receptor activator of NF-κB (RANK) and its ligand (RANKL), IL-1, IL-6, IL-10, TGF-β, TNF, CD80, CD86, CD40, macrophage colony-stimulating factor (M-CSF), nuclear factor of activated T cell cytoplasmic (NFATc), and vitamin D (see Table 103-4 for roles and function). Many of these factors can be categorized into one of two categories—those with the overall effect of inducing osteoclastogenesis, and those that inhibit osteoclastogenesis. In addition, factors involved in cell survival and apoptosis such as Blimp-1 and Bcl-6 may also play a role. RANKL is expressed on osteoblasts and is critical for the differentiation and proliferation of osteoclasts. Because transcription of factors involved in the regulation of bone homeostasis is often influenced by glucocorticoids, this mechanism may begin to explain why steroids may be associated with osteonecrosis. The role of the innate immune system has recently come into play as well because investigators reported an upregulation in Toll-like receptor 4 signaling pathways in animal models of osteonecrosis, leading to activation of osteoclasts.[103,104]

The action of glucocorticoids is mediated by the glucocorticoid receptor, which is present on many cell types, including osteoclasts, osteoblasts, osteocytes, and cartilage. Binding of glucocorticoids to its receptor leads to the anti-inflammatory activity known to be a function of steroids. One mechanism by which this anti-inflammatory effect is mediated is through transcription of genes that inhibit the synthesis of inflammatory mediators.

## Osteoblast/Osteoclast Balance

Any disturbance in the normal homeostasis between bone deposition and bone resorption can lead to bone disease. Moreover, defective bone deposition or bone resorption in which new bone is formed in an aberrant manner can lead to disease. Alcohol can affect the ability of mesenchymal stem cells to differentiate into osteogenic lineages. During hip replacement surgery, the bone marrow in the proximal head of femurs was isolated in 33 patients with either femoral neck fractures or alcohol-induced osteonecrosis. The cells from femurs of patients with alcohol-induced osteonecrosis showed a reduced ability to differentiate into osteoblasts.[105] A subsequent study compared mesenchymal stem cells from patients with hip osteoarthritis, idiopathic osteonecrosis, and nontraumatic osteonecrosis associated with steroid or alcohol use. In idiopathic and alcohol-induced osteonecrosis, the ability of mesenchymal stem cells to differentiate into osteoblasts was decreased, but in steroid-induced osteonecrosis, it was elevated, although not to a statistically significant level. The adipogenic differentiation ability was similar in all four groups.[106]

In rats fed a diet of alcohol and glucose, lower bone mineral content and density were detected compared with control subjects. In hamsters, alcohol led to thinning of the trabeculae of the distal part of the femur. Cytologic effects included mitochondrial swelling in osteoblasts and

**TABLE 103-4** Role and Function of Immune Factors in Osteoimmunology

| Immune Factor | Ligand | Cellular Source | Function in Bone Homeostasis | OC | Immune Function |
|---|---|---|---|---|---|
| RANK | RANKL | Osteoclasts, dendritic cells | Upon binding to RANKL, signals differentiation into osteoclast | ↑ | RANKL-RANK binding leads to dendritic cell activation |
| RANKL | RANK | Osteoblasts, T helper cells | Activation of osteoclasts; overproduction can result in RA or PA | ↑ | Dendritic cell maturation |
| OPG | RANKL | | Decoy receptor for RANKL | ↓ | |
| M-CSF | CSF-1 receptor | Osteoblasts, macrophages, bone fibroblasts, stromal cells | Stimulates osteoclastogenesis | ↑ | Influences hematopoietic stem cells to differentiate into macrophages |
| TNF | TNF receptor | Macrophages, lymphocytes, mast cells, and many others | Stimulates osteoclastogenesis | ↑ | Influences multiple signaling pathways, including NF-κB, death signaling, and MAP kinase pathway |
| TGF-β | TGF-β receptor | Multiple cell lines | Induction of apoptosis | ↑ | Regulatory role, blocks activation of lymphocyte- and monocyte-derived phagocytosis |
| Blimp-1 | Bcl-6 promoter | Plasmablasts, plasma cells | Binds to Bcl-6 promoter, suppression expression | ↑ | Inhibits Tfh cell differentiation in mice[254] |
| Bcl-6 | ? | Germinal center B cells | Inhibits osteoclastogenesis | ↓ | Stimulates Tfh cell differentiation in mice |
| IL-1 | IL-1R | Macrophages, monocytes, fibroblasts, dendritic cells | Directly activates RANK signaling to promote osteoclastogenesis[255] | ↑ | Pro-inflammatory cytokine, endogenous pyrogen |
| IL-6 | IL-6R | Osteoblasts | Activation of osteoclastogenesis | ↑ | Pro-inflammatory cytokine |
| IL-10 | IL-10Rα | Monocytes, lymphocytes | Suppress bone resorption | ↓ | Anti-inflammatory cytokine, blocks NF-κB activity, regulatory cytokine |
| Vitamin D | VDR | Osteoblast, monocyte/ macrophage | Facilitate adhesion of osteoclast precursor to osteoblast[256] | ↑ | Cell proliferation and differentiation |
| Estrogens | Estrogen receptor | Ovarian follicle cells | Reduces osteoclast IL-1 responsiveness and cell survival,[257] stimulates osteoprotegerin | ↓ | Angiogenesis, endothelial healing |
| IL-17 | IL-17R | T cells | May have opposing roles of bone protection and bone loss[258] | ↑↓ | Pro-inflammatory cytokine |
| IL-18 | IL-18R | Macrophages | Inhibits TNF-mediated osteoclastogenesis in a T cell–independent manner | ↓ | Pro-inflammatory cytokine, works in synergy with IL-12 |

Examples of some of the factors involved in bone metabolism. In addition to the factors listed, others that play a role, either by themselves or in conjunction with other factors. The factors listed may have many other functions. Only select functions are listed.

Bcl-6, B cell lymphoma 6 protein; Blimp, B lymphocyte–induced maturation protein 1; CSF-1, colony-stimulating factor 1; M-CSF, macrophage colony-stimulating factor; NF-κB, nuclear factor-κB; MAP, mitogen-activated protein; OC, osteoclastogenesis; OPG, osteoprotegerin; PA, psoriatic arthritis; RA, rheumatoid arthritis; RANK, receptor activator for NF-κB; RANKL, receptor activator for NF-κB ligand; Tfh, T follicular helper cell; TGF-β, transforming growth factor-β; VDR, vitamin D receptor.

osteocytes. Partial osteonecrosis of the femoral head was detected in Merino sheep that were injected with ethanol. In humans, alcohol causes increased plasma calcium levels, decreased osteocalcin and circulating parathyroid hormone levels, reduced serum calcitriol, reduced bone volume, and an increased number of osteoclasts.

Alterations in osteoblast function may also contribute to the pathogenesis of osteonecrosis. In one study, osteoblasts were obtained from bone biopsy specimens from the intertrochanteric region of the femur and the iliac crest of 13 patients with osteonecrosis and 8 patients with hip osteoarthritis. Cell replication was measured on the basis of proliferation rate in secondary culture. Levels of alkaline phosphatase activity, collagen synthesis, and sensitivity to 1,25-dihydroxyvitamin $D_3$ were measured. The results indicated that although differentiation was not affected, the proliferation rate of osteoblastic cells was reduced in samples obtained from the patients with osteonecrosis compared with patients who had osteoarthritic hips.[107]

## Apoptosis and Osteonecrosis

Glucocorticoids can also act via their action on apoptosis of immune and bone cells. When prednisolone was administered to mice for 27 days, increased metaphyseal apoptotic activity of both osteoblasts and osteoclasts was noted.[108] The result was decreased bone turnover, density, and formation, increased formation of cancellous bone, and decreased trabecular width. The decreased bone turnover can be explained by the reduced osteoclast survival, and the reduction in trabecular width can be explained by a decrease in osteoblasts. An accumulation of apoptotic elements was also found in the region of the "fracture crescent" in the femurs of patients treated with glucocorticoids. On the

other hand, glucocorticoids may also increase osteoclast survival, leading to increased bone loss. Clearly, the effect of osteoclast survival on bone disease is more complicated than at first glance, and it involves the interaction of the osteoclast with the osteoblast. Because osteoblasts are also responsible for osteoclast differentiation under the right circumstances, a significant feedback system exists that maintains bone homeostasis.

Osteocyte death is also a feature of osteonecrosis. In a rat model, ischemia caused an induction in the expression of stress proteins, oxygen-regulated protein (ORP150), and hemoxygenase 1 (HO1). Induction of ischemia in these rates caused DNA fragmentation and the presence of apoptotic bodies in chondrocytes, bone marrow cells, and osteocytes.[109] Both alcohol and corticosteroids can induce osteocyte apoptosis, possibly via aberrations in lipid metabolism.

## Lipids and Osteonecrosis

Rabbits that were fed alcohol were found to have fatty infiltration of the liver and adipogenesis in the bone marrow. Increases in fat cell hypertrophy and proliferation, as well as a decrease in hematopoiesis in the subchondral head, were observed. Osteocytes contained triglyceride deposits, and an increase in empty osteocyte lacunae was noted. Alcohol also primarily triggered differentiation of bone marrow stromal cells into adipocytes in a dose-dependent manner. Intra-cellular lipid deposits led to the death of osteocytes.

In corticosteroid-induced osteonecrosis, the alteration in lipid metabolism parallels that of alcohol-induced osteonecrosis. In both cases, fatty infiltration of osteocytes has been postulated to occur.[110-112] Table 103-5 lists lipid-altering effects of corticosteroids and alcohol. In addition, interosseous venous stasis affects the interosseous microcirculation, which can lead to hemodynamic and structural changes in the femoral head. The resulting decrease in blood flow leads to osteonecrosis. In chickens treated with steroids, fatty infiltration of the liver and fat cell hypertrophy and proliferation in the femoral head occurred concurrently 1 week after the initiation of steroids. As in the case of alcohol-induced osteonecrosis, adipocytes contained triglyceride vesicles. In rabbits treated with steroids, it was found that interosseous pressure was increased and the size of bone marrow fat cells was larger than in control rabbits.[113] A histologic study of acetabular and proximal femoral bone in osteonecrosis of the femoral head revealed that osteonecrosis is more extensive in corticosteroid-induced compared with alcohol-induced or idiopathic osteonecrosis.[114] The reason for this phenomenon is unknown.

In ONJ, bisphosphonates inhibit protein prenylation via inhibition of the enzyme farnesyl diphosphate synthase. The normal lipid metabolism of pathways that regulate cytoskeletal integrity and osteoclastogenesis such as Rho, Rac, and Ras is disrupted, which is one of the mechanisms by which bisphosphonates exert their intended action, but their ability to disrupt normal regulation of bone metabolism may instead lead to osteonecrosis.

**TABLE 103-5** Lipid-Altering Effects of Steroids and Alcohol

| Fatty infiltration of bone marrow |
| Fat emboli |

## Coagulation and Osteonecrosis

The hyperlipidemia, increased serum free fatty acids, and increased prostaglandins that are associated with alcohol-induced osteonecrosis may potentially trigger vascular inflammation and coagulation. Other triggers for intravascular coagulation include atherosclerosis and arteriolar fibroid degeneration. Jones[115] proposed that the progression of osteonecrosis from stage 1A to 1B is linked to an inability to clear procoagulants from blood or tissue. He proposed that decreased clearance of procoagulants leads to persistent levels of tissue thromboplastin and thus to arteriolar thrombosis, vascular stasis, free fatty acid–induced endothelial damage, and hypercoagulability. Studies have shown that patients with osteonecrosis had a much higher frequency of having at least one or two abnormal coagulant levels compared with normal control subjects. Of patients with osteonecrosis, 82% had at least one and 47% had at least two abnormal procoagulant levels. In normal control subjects, only 30% had one abnormal procoagulant level and only 2.5% had two or more abnormal levels. The procoagulants measured included free protein S, protein C, lipoprotein A, homocysteine, plasminogen activator inhibitor, stimulated tissue plasminogen activator, anti-cardiolipin antibodies (IgM and IgG), and resistance to activated protein C.[116]

In addition, both thrombophilia and hypofibrinolysis have been associated with osteonecrosis. Hypofibrinolysis leads to an increased likelihood of clot formation, and thrombophilia results in a decreased ability to lyse clots. Hypofibrinolysis is yet another mechanism by which corticosteroids lead to osteonecrosis—high-dose steroids lead to increased plasma plasminogen activator inhibitor, decreased tissue plasminogen activator activity, and inhibition of the fibrinolytic pathway, thus leading to a higher risk for clot formation. There is an early indication that coagulation abnormalities may play a significant role in corticosteroid-induced osteonecrosis in patients with SARS.[117,118]

## Oxidative Stress and Osteonecrosis

Alcohol consumption is associated with reduced superoxide dismutase activity. Alcohol has deleterious effects on muscle, including increased oxygen free radical–related damage, reduced myocardial contractility, defective mitochondrial function, and increased tissue enzymes.[119] When rabbits were injected with methylprednisolone, elevations in 8-hydroxy-2′deoxyguanosine, a marker of DNA oxidative injury, were observed.[120-123] These elevations coincided with the development of osteonecrosis. A polymorphism in nitric oxide synthase (NOS), which will be subsequently described, was also associated with the development of

osteonecrosis. The relationship between osteonecrosis and oxidative injury leads one to wonder if corticosteroid-induced osteonecrosis can be prevented or lessened in severity by simultaneous or prophylactic administration of antioxidants.

## Radiation and Osteonecrosis

An association between radiation exposure and osteonecrosis was reported as early as 1950.[124] The earliest reports involved primarily ONJ. Most of the evidence for radiation as a cause of osteonecrosis is derived from case reports. One of the more recent larger studies involved a case-control study to investigate risk factors for ONJ, in which 191 patients with ONJ and 573 control subjects were enrolled from 119 dental practices. The odds ratio for radiation exposure was 24.1 (4.9 to 118.4). However, when patients with cancer were excluded, the association between ONJ and radiation exposure no longer existed as an independent risk factor.[125]

Exposure to radiation may result in damage to vascularity of bone and lead to osteonecrosis in a dose-dependent manner. In particular, osteonecrosis after radiation for neoplasms is well documented and particularly affects the femoral head and the mandible. Concomitant administration of chemotherapy can accentuate the risk of osteonecrosis in patients who are receiving radiation, particularly elderly women.

Interestingly, an animal model of osteonecrosis induced by high-intensity focused ultrasound (HIFU) was developed to determine if HIFU could be used to generate osteonecrosis for animal studies. In this model, high-power acoustic energy up to 1000 W/cm$^2$ focused directly at bone was able to induce osteonecrosis of the femoral head in a canine model via the creation of a thermal injury. Typical diagnostic ultrasound transducers generally deliver intensities ranging between 0.1 to 100 W/cm$^2$, although HIFU has been studied for use in cancer and can reach 100 to 10,000 W/cm$^2$. This finding raises the possibility of ultrasound-induced osteonecrosis in humans in real-life clinical settings, although this possibility is far from substantiated.[126] The proposed mechanism by which ultrasound can induce osteonecrosis is through thermal damage induced by osteocyte damage and vascular thrombosis.

## Nitric Oxide Synthase and Osteonecrosis

Glucocorticoids can cause derangements in vascular responsiveness to vasoactive substances such as nitric oxide. Endothelial NOS (eNOS) stimulates the production of nitric oxide. Nitric oxide regulates vascular "tension" by acting as a vasodilator, inhibiting mononuclear adhesion to endothelial cells and preventing platelet aggregation. A defect in this activity can lead to increased vascular resistance and disruption to downstream blood flow, resulting in osteonecrosis.[127]

## Multihit Hypothesis

Other proposed mechanisms of osteonecrosis involve endothelial cell injury,[128] abnormal angiogenesis and repair mechanisms,[129] the effects of vasoactive substances,[130] activity of hepatic cytochrome P450 3A4,[131] and intramedullary hemorrhage.[132] Multiple mechanisms may occur simultaneously. Kenzora and Glimcher[133] were the first to introduce the concept of cumulative stress. Corticosteroid-induced osteonecrosis seems to occur with greater frequency in patients who have significant underlying illness such as systemic lupus erythematosus[134] or transplantation and less frequently or never in patients who are not chronically ill but are taking steroids for an acute event such as a head injury. Recent observations that corticosteroids induce osteonecrosis in patients with SARS further support the notion that more than one insult to the bone or surrounding tissue may be necessary to precipitate osteonecrosis. For each of the known associations of osteonecrosis, different mechanisms may predominate, such as lipid anomalies and apoptosis of osteoblasts in steroid-induced osteonecrosis, as well as elevated intraosseous pressures and coagulation abnormalities in dysbaric osteonecrosis, but additional factors may be necessary to precipitate osteonecrosis. The accumulated cell stress theory suggests that when the damaging effects of multiple events are aligned, similar to the Swiss-cheese model of risk assessment,[135,136] the involved bone is unable to recover from the chronic stress and osteonecrosis ensues.

## Microorganisms and the Microbiota in Osteonecrosis: Environmental Considerations

It has been postulated that infection is a major risk factor in the development of ONJ. Studies have attempted to define the role of microorganisms and the host response to infection as potential mechanisms for disease development and progression. Pushalkar and colleagues[137] compared microbial diversity in a small set of patients who took bisphosphonates and did or did not have osteonecrosis, as well as in normal control subjects. These investigators found less bacterial diversity in the bisphosphonate-related ONJ (BRONJ) group compared with the others, but with a predominant presence of Firmicutes. They also found lower levels of myeloperoxidase but higher levels of the proinflammatory cytokines IL-6 and TNF in the BRONJ cohort compared with control subjects. Furthermore, polymerase chain reaction analysis revealed downregulation of nucleotide-binding oligomerization domain–containing protein 2 (NOD-2) and cathepsin G and upregulation of secretory leukocyte protease inhibitor, proteinase 3, and conserved helix-loop-helix ubiquitous kinase. The respective roles of the microorganism environment itself versus the host innate immune response to this environment are still to be elucidated.[137]

In yet another study investigating the microbacterial environment in patients with BRONJ, Wei and colleagues[138] found that the predominant species in osteonecrosis lesions in patients with BRONJ included *Stretococcus* (29%), *Eubacterium* (9%), and *Pseudoramibacter* (8%) compared with the control group, in whom the most common species found were *Parvamonas* (17%), *Streptococcus* (15%), and *Fusobacterium* (15%). Wei and colleagues[138] also found that in patients with BRONJ, hematoxylin-eosin staining revealed that the bacteria were layered and packed into the scalloped edges of BRONJ bone, suggesting the role of biofilms as a potential risk factor for the development of BRONJ.[138]

Scanning electron microscope images have shown the presence of biofilms in BRONJ lesions.[139] It should also be noted that bacteria are not the only pathogens found in BRONJ lesions; fungi, especially *Candida* and *Actinomyces*, have also been found in lesions of patients with ONJ.[140]

### Genetic and Epigenetic Considerations

The degree to which genetics and the environment play a role in the pathogenesis of osteonecrosis is the subject of an ongoing investigation. Certainly, single nucleotide polymorphisms have been noted in a number of genes that may be associated with osteonecrosis. It has been argued that eNOS is an important player in the development of osteonecrosis. Nitric oxide may have beneficial effects on three systems involved in osteonecrosis—namely skeletal, vascular, and thrombotic. Each of these systems may be targets for proposed mechanisms of pathogenesis of osteonecrosis. A comparative analysis of the 26–base pair repeat polymorphism in intron 4 and the Glu298Asp polymorphism in exon 7 of the eNOS gene in patients with idiopathic, steroid-induced, and alcohol-induced osteonecrosis and normal control subjects was performed.[141] The frequency of the homozygous 4a allele was found to be higher in patients with idiopathic osteonecrosis compared with control subjects. The frequency of the 4a/b allele was found to be higher in all types of osteonecrosis when compared with control subjects. The 4a allele is known to be associated with reduced synthesis of eNOS, suggesting that nitric oxide may play a protective role with regard to the development of osteonecrosis.

Forty-one percent of patients with osteonecrosis compared with only 20% of control subjects were homozygous for the 4G/4G mutation in the plasminogen activator inhibitor-1 *(PAI-1)* gene.[142] This mutation causes increased hypofibrinolytic plasminogen activator inhibitor activity, resulting in decreased stimulated plasminogen activator activity. This observation lends support to the theory that procoagulants may play a significant role in the pathogenesis of osteonecrosis. A polymorphism in the *PAI-1* gene has also been reported to be predictive of osteonecrosis in children with acute lymphoblastic leukemia.[143]

Genetic variations in the type and levels of lipoprotein(A) have been linked to osteonecrosis. Apolipoprotein(A) (Apo[A]) is involved in lipid metabolism and the coagulation systems, and the Apo(A) low-molecular-weight phenotype is associated with an increased risk of osteonecrosis.[144-146] Polymorphisms in the promoter for vascular endothelial growth factor (VEGF) and in the receptor for IL-23 were associated with osteonecrosis in the Korean population,[147-149] reflecting the significance of the association of osteonecrosis with vascular disorders and autoimmune diseases, respectively.

Epigenetic modulation of gene expression has recently been recognized to affect more than half of all human genes. Several pathways exist for epigenetic transformation, including DNA methylation and demethylation, histone modifications such as acetylation and deacetylation, and microRNAs. MicroRNAs are short 21- to 23-nucleotide RNA molecules that bind to messenger RNA of the promoter region of genes and serve a regulatory function. Overexpression of certain microRNAs therefore may affect the expression of genes coding for various mediators of disease, such as cytokines or growth factors. In 2012, Yamasaki and colleagues[150] demonstrated that microRNA-210 is upregulated in the cells surrounding osteonecrotic bone. Furthermore, microRNA-210 is known to play a role in angiogenesis. Accompanying the upregulation of microRNA-210 in patients with osteonecrosis were also increased expression of VEGF and matrix metalloproteinase (MMP)-2 and -7 when compared with patients who had osteoarthritis.[150]

Other microRNAs such as microRNA-29a and microRNA-548d-5p have also been shown to play a role in regulation of bone resorption and osteogenesis.[151,152] MicroRNA-17-5p, which is known to play a role in cancer cell proliferation and invasion, was evaluated to test whether it also plays a role in osteoblast differentiation. The investigators found that expression of this microRNA was lower in patients who had osteonecrosis compared with patients who had osteoarthritis. This finding was accompanied by a facilitation in the differentiation of HMSC-bm cells, which is thought to be mediated by the action of microRNA-17-5p on expression of β-catenin and a subsequent increase in COL1A1.[153] MicroRNA profiles identified 27 microRNAs that were differentially expressed in patients with osteonecrosis of the femoral head. Fifteen were overexpressed, and 12 were underexpressed in patients with osteonecrosis when compared with either patients who had systemic lupus erythematosus or healthy control subjects.[154] The differentiating nature of microRNA profiles may play a future role as disease biomarkers.

Small interfering RNAs (siRNAs) have been shown to play a potential role in disease management. It is known that glucocorticoids may act in osteonecrosis by virtue of their ability to induce overexpression of the peroxisome proliferator-activated receptor γ (PPARγ) gene, leading to adipogenesis, which has already been discussed as a potential mechanism for osteonecrosis. In a rabbit model for steroid-induced osteonecrosis, siRNAs targeting PPARγ were able to reduce levels of PPARγ expression and increase levels of Runx2 and osteocalcin in rabbits treated with dexamethasone plus a recombinant adenovirus shuttle vector carrying an siRNA targeting PPARγ, compared with rabbits treated with dexamethasone alone. Treatment with dexamethasone plus the recombinant adenovirus shuttle vector led to amelioration of the marrow necrosis, adipocyte hypertrophy and proliferation, diminished hematopoiesis, thinner and sparse trabeculae, and an increased number of empty osteocyte lacunae in the femoral head seen in rabbits that only received dexamethasone or in combination with an irrelevant shuttle vector.[155] These studies, although in their early stages, offer hope for novel treatments based on pathogenesis and the physiologic and cellular derangements that are risk factors for the development of osteonecrosis.

## DIAGNOSIS

### History and Physical Examination

The diagnosis of osteonecrosis is generally made via the history, because many patients may not present until hip pain develops. By the time the patient is clinically symptomatic, the disease may be quite advanced. Therefore a

high index of suspicion is necessary for all patients taking oral or parenteral steroids. The following information should be elicited: any history of trauma; underlying disease; alcohol use; tobacco use; current medications; past medications; history of joint anomalies; presence of pain or limitation of motion; involvement in sports, especially high-impact sports; occupational history; gestational history; and the presence of liver disease or lipid abnormalities.

Physical examination includes palpating the lateral aspect of the hip for tenderness and identifying limp, leg-length discrepancy, the presence of masses, abnormal gait, muscle strength, and range of motion. The Harris hip score is frequently used to evaluate hip function and is also useful in monitoring the effectiveness of treatment (Figure 103-2).[156-158] The Harris hip score is a multidimensional observational assessment based on eight items that address pain,

**Hip Joint Evaluation System**

| **Date of assessment:** | **Name:** | | **Medical record #:** | **DOB:** |
|---|---|---|---|---|
| **Pain** | **Distance walked** | **Activities-shoes, socks** | **Public transportation** | **Limp** |

walking function, daily activity, and range of motion. Scores range from 0 (maximum disability) to 100 (no disability).

## Diagnostic Imaging

When the diagnosis of osteonecrosis is suspected clinically, it can be confirmed by imaging studies. In the early stages of osteonecrosis, plain radiographs may be completely normal. The earliest radiographic sign of osteonecrosis is the presence of a radiolucent crescent-shaped rim along the contour of the femoral head (the crescent sign) (Figure 103-3). This appearance on radiographs is the result of structural collapse of a necrotic segment of subchondral trabecular bone. At this stage, the disease is already irreversible. Later, radiographs will begin to show sclerotic changes (Figure 103-4). The appearance of radiographic "density" is secondary to compression of bone trabeculae after microfracture of the nonviable bone, calcification of detritic marrow, and repair of the necrotic area by deposition of new bone, the so-called "creeping substitution." Flattening of the articular surface of bone is a sign of further bone collapse (Figure 103-5). To show best the radiographic appearance of osteonecrosis in the femoral head and to better visualize the extent of the necrotic lesion, anteroposterior and frog-leg lateral radiographs of the hip should be obtained.

Skeletal scintigraphy (i.e., a radionuclide bone scan) using technetium-labeled diphosphonates has also been

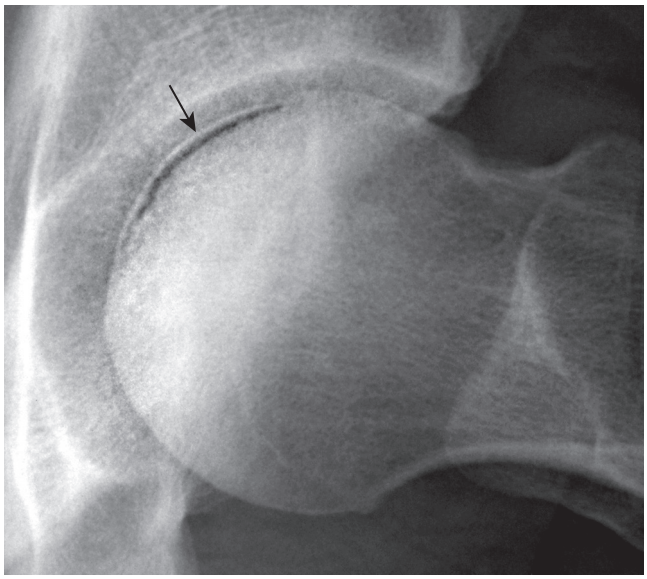

**Figure 103-3** A radiolucent crescent in the subchondral region of the left femoral head *(arrow)* is an early radiographic sign of osteonecrosis.

**Figure 103-5** Increased density of the femoral head, loss of the normal spherical shape, and flattening of the superior aspect are characteristic radiographic features of osteonecrosis.

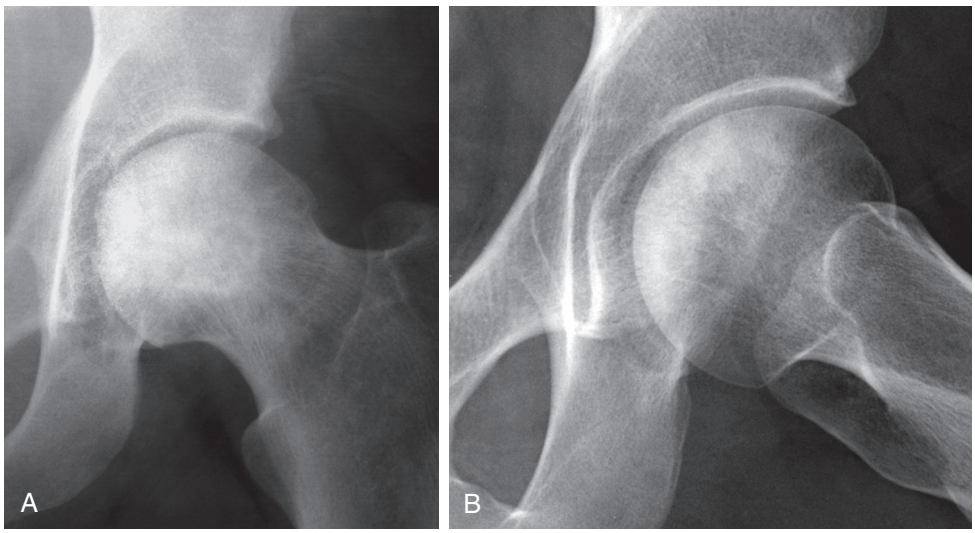

**Figure 103-4** Anteroposterior **(A)** and frog-leg lateral **(B)** views of the left hip show sclerotic changes of the femoral head typical of advanced osteonecrosis.

used to diagnose osteonecrosis. The use of this technique in the early diagnosis of this condition depends on the increase of osteoblastic activity and blood flow in the early stages of osteonecrosis. In an advanced stage of disease, the appearance may be one of increased activity in a subchondral distribution as a result of osteoblastic activity at the reactive interface around the necrotic segment; however, the center of the osteonecrotic lesion may show much less radionuclide uptake (Figure 103-6) or even a complete lack of activity, reflecting decreased metabolism in the necrotic focus as a result of interruption of the blood supply.[7]

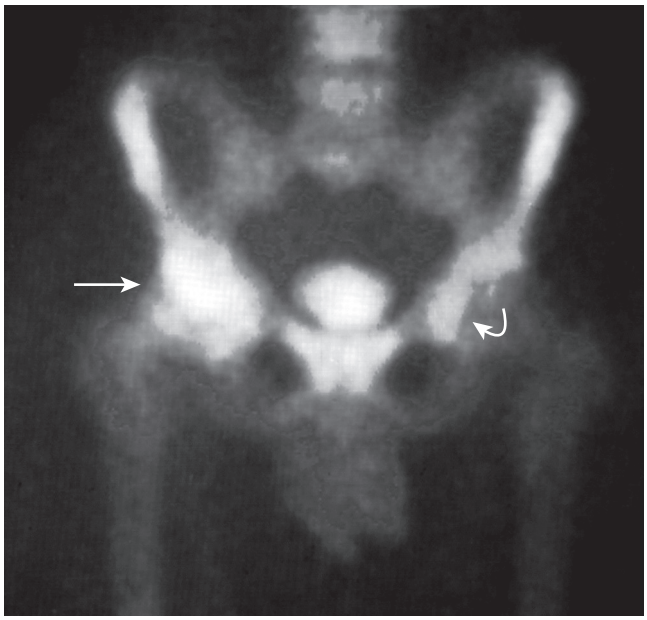

**Figure 103-6** Bone scintigraphy of osteonecrosis of both femoral heads using technetium 99m methylene diphosphonate shows moderate uptake of the radiopharmaceutical agent at the site of the osteonecrotic segment in the right femoral head and markedly increased uptake at the site of bone repair *(straight arrow)*. The left femoral head *(curved arrow)* exhibits early-stage disease.

In addition to bone scintigraphy, single-photon emission computed tomography maximizes sensitivity. A study comparing conventional radiography, MRI, computed tomography (CT), and a Tc 99m MDP three-phase bone scan in diagnosing bisphosphonate-associated osteonecrosis of the jaw showed that CT and MRI best defined the extent of the disease but that a bone scan best identified disease at an early stage. A bone scan could be an excellent screening tool for the diagnosis of osteonecrosis before further characterization of the lesions using CT or MRI.[159]

CT allows more detailed examination of the femoral head. A star-shaped structure, formed by weight-bearing bone trabeculae, gives the appearance of an asterisk on a CT scan (the asterisk sign).[160-162] This asterisk undergoes a characteristic change in ischemic bone necrosis of the femoral head, and this change was considered important for early detection of osteonecrosis. At a later stage, the collapse of necrotic bone can be well visualized (Figure 103-7).

Currently, MRI is the gold standard for imaging of osteonecrosis. Most of the staging systems for osteonecrosis are now based on MRI appearance (Table 103-6). MRI of osteonecrosis can show changes earlier than conventional radiography or CT. It can also detect bone marrow edema, a feature sometimes seen in the early phases of osteonecrosis that is not visible on conventional radiography or CT.

The typical MRI findings in osteonecrosis are intermediate or low signal intensity on T1-weighted images and high signal intensity on T2-weighted and other water-sensitive sequences (Figure 103-8). As the disease progresses, the subchondral necrotic lesion is surrounded by a low signal line on T1-weighted images and a high signal line is seen on T2-weighted images, central to the low signal line, producing the "double-line" sign (Figure 103-9). In advanced osteonecrosis, the necrotic segment exhibits low signal intensity on both T1-weighted and T2-weighted images (Figure 103-10). MRI is performed in the sagittal, coronal, and axial planes and includes T1- and T2-weighted sequences. Although excellent correlation exists between histologic findings and MRI appearance (see Table 103-6),

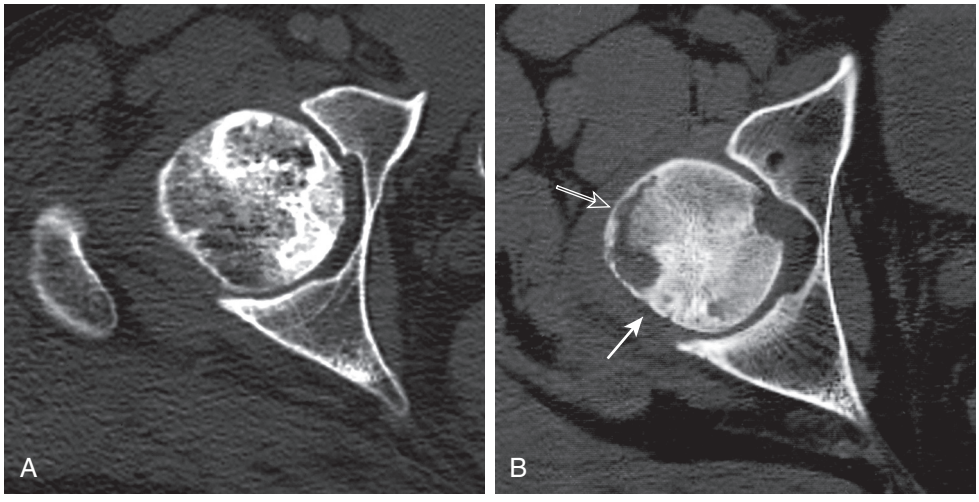

**Figure 103-7** **A,** A computed tomography scan shows osteonecrosis of the femoral head. Although several sclerotic foci are present within the trabecular bone, the integrity of the osseous structures is preserved and the femoral head exhibits a normal spherical shape. **B,** In a more advanced stage of osteonecrosis of the femoral head, note increased sclerosis in the posterior aspect *(solid arrow)* and subchondral collapse of necrotic bone anterolaterally *(open arrow)*.

**TABLE 103-6** MRI Changes and Their Correlation with Histology in Osteonecrosis

| Type of Appearance | Category of Observations | Histology | MRI Appearance |
|---|---|---|---|
| A | Fat-like | Premature fatty marrow development in the femoral neck or intertrochanteric region | Normal fat signal; sclerotic margin may be seen; circumscribing lesion |
| B | Blood-like | Bone resorption; replacement by vascular granulation tissue | High signal intensity of inner border; low signal intensity of the surrounding rim |
| C | Fluid-like | Bone marrow edema | Diffusely decreased signal on T1-weighted images; high signal on T2-weighted images |
| D | Fibrotic | Sclerosis as a result of reinforcement of existing trabeculae at the margin of live bone (repair tissue interface) | Decreased signal on T1- and T2-weighted images |

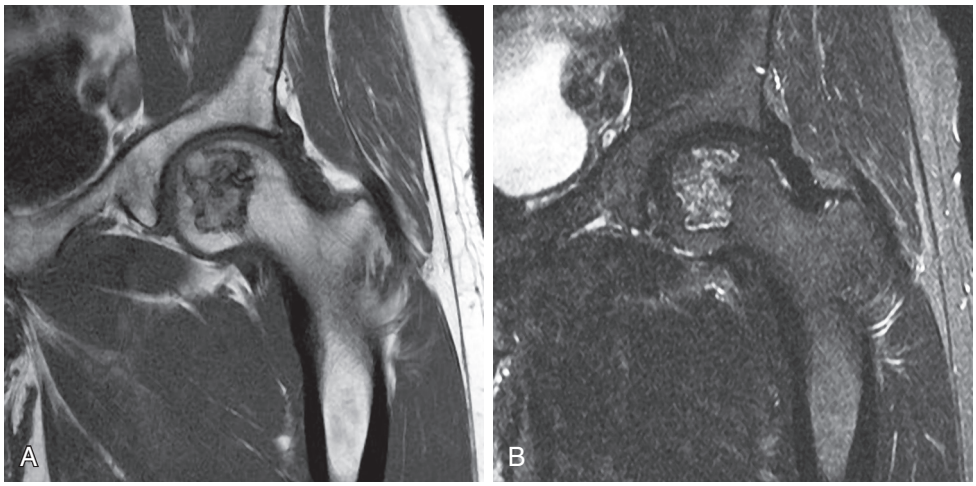

**Figure 103-8** **A,** On a T1-weighted coronal MRI of the left hip, the osteonecrotic segment in the subchondral portion of the femoral head shows low signal intensity. **B,** On a T2-weighted coronal image, the necrotic bone exhibits high signal intensity, surrounded by a sclerotic low signal rim. The low signal intensity rim surrounds a high signal intensity rim, representing the double-line sign (see also Figure 103-9). Note that the signal intensity of the necrotic area is heterogeneous in both the T1- and T2-weighted sequences.

**Figure 103-9** A coronal T2-weighted MRI scan of the right femoral head shows the double-line sign *(arrow),* which is characteristic for osteonecrosis: low signal at the periphery of the lesion and a high signal band located more centrally.

in most cases the necrotic area is composed of a variety of tissue, including areas of fibrosis and necrosis mixed with areas of blood and edema, depending on the age of the infarct. Therefore the MRI signal of the necrotic area is often very heterogeneous (see Figure 103-8), and as a result, this classification is of little clinical value. The low signal intensity band in the periphery of the osteonecrotic area correlates with a sclerotic band seen on radiographs and CT and often has a serpiginous appearance. When the osteonecrosis involves a long bone, this serpiginous band or line has been termed "smoke in a chimney."

MRI is an important tool in determining the extent of femoral head involvement in osteonecrosis. Three techniques are used to evaluate the extent of this involvement. The first is estimating head involvement. This method was first proposed by Steinberg and colleagues[163] in 1984, and it is defined by the appearance of abnormal signals on T1-weighted images. The degree of head involvement was classified into three categories: less than 15%, 15% to 30%, and greater than 30%. The second method used to evaluate the extent of involvement is the index of necrotic extent, which is determined by measuring the angle created by the extent of subchondral involvement. Lesion size was estimated using a "necrotic arc angle," defined by the angle of

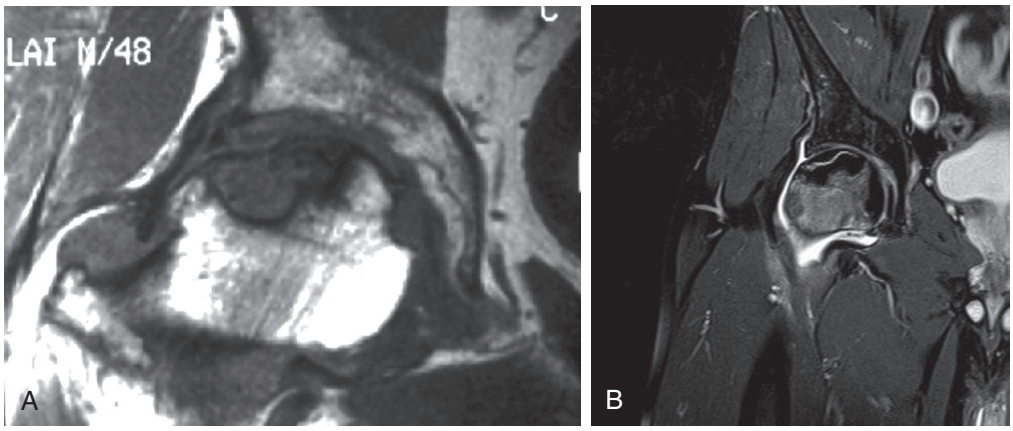

**Figure 103-10** Advanced osteonecrosis of the femoral head in two different patients. **A**, A coronal T2-weighted MRI scan demonstrates osteonecrosis of the femoral head with a subchondral fracture shown as a high signal intensity undulating subchondral line. Note the flattening of the femoral head and the presence of bone marrow edema in the femoral neck and joint effusion. **B,** A coronal T1-weighted MRI scan in another patient demonstrates low signal intensity of the femoral head with partial collapse. Note the early degenerative changes with a small marginal osteophyte of the femoral head, chondral loss, and a superior labral tear.

**TABLE 103-7** Comparative Sensitivity and Specificity of Diagnostic Radiologic Imaging Modalities in Osteonecrosis

| Radiologic Imaging | Earliest Sign Seen | Histologic Correlation | Stage | Degree of Specificity |
|---|---|---|---|---|
| Conventional radiograph | Crescent sign | Sclerotic rim of reactive bone | 2 | High |
| CT scan | Asterisk sign | Sclerotic rim surrounding a mottled area of osteolysis and sclerosis | 2 | High |
| MRI | Low signal intensity on T1-weighted images; high signal intensity on T2-weighted images | Bone marrow edema | 1 | High |
| Skeletal scintigraphy | Decreased uptake in subchondral distribution ("cold spot") | Osteonecrosis | 1 | Low |
| | Increased uptake in subchondral distribution ("hot spot") | "Creeping substitution" | 2 | Low |

the arc of the necrotic segment from the center of the femoral head. Two angles are obtained: "A," representing the necrotic arc seen on midcoronal images, and "B," representing the necrotic arc angle seen on midsagittal images. The index is a compilation of these two angles. The third method is a variation of the second, in which the angle is identified not on midcoronal or midsagittal images but on the image that shows the maximum lesion size in the sagittal and coronal planes. It is thought that this method would correct for the underestimation that may be inherent in the second method.

Table 103-7 shows a comparison of various imaging techniques used in the diagnosis and staging of osteonecrosis. Hip arthroscopy is also used in the staging of osteonecrosis. In a study comparing radiography, MRI, and arthroscopy, only moderate correlation was found among the three methods. Arthroscopy was able to detect osteochondral degeneration that was not detected by radiography or MRI in 36% of collapsed heads. Figure 103-11 is an algorithm for the diagnosis of osteonecrosis. Although the femoral head is one of the most common locations (see Figure 103-10), osteonecrosis can be seen in practically any bone. Additional examples of MRI imaging of Kienböck's disease and osteonecrosis of the knee are illustrated in Figures 103-12 and 103-13, respectively.

## Markers of Disease

The ability to find consistent and reliable markers of disease is always a welcome tool for diagnosis, determination of the extent of the disease, or even determination of the risk of acquiring the disease. The measurement of serum and urine carboxy-terminal cross-linking telopeptide of type I collagen (CTX-1), a marker of bone resorption, has been proposed as a method of evaluating the risk of ONJ as a result of bisphosphonate usage, although they are not commonly measured in the clinical setting. A serum osteocalcin level, which is easier to obtain, is another marker for bisphosphonate-related ONJ that has been suggested as a risk predictor because levels were significantly lower in the osteonecrosis group compared with a control group.[164]

# OUTCOME

The natural history of osteonecrosis depends on the size of the infarcted segment, the site of occurrence, and the clinical and radiologic staging of the disease. At the onset of the disease, range of motion may be well preserved but gradually deteriorates over time. In the early stages of the disease, when it is still reversible, patients may be asymptomatic; many patients therefore present with advanced disease.

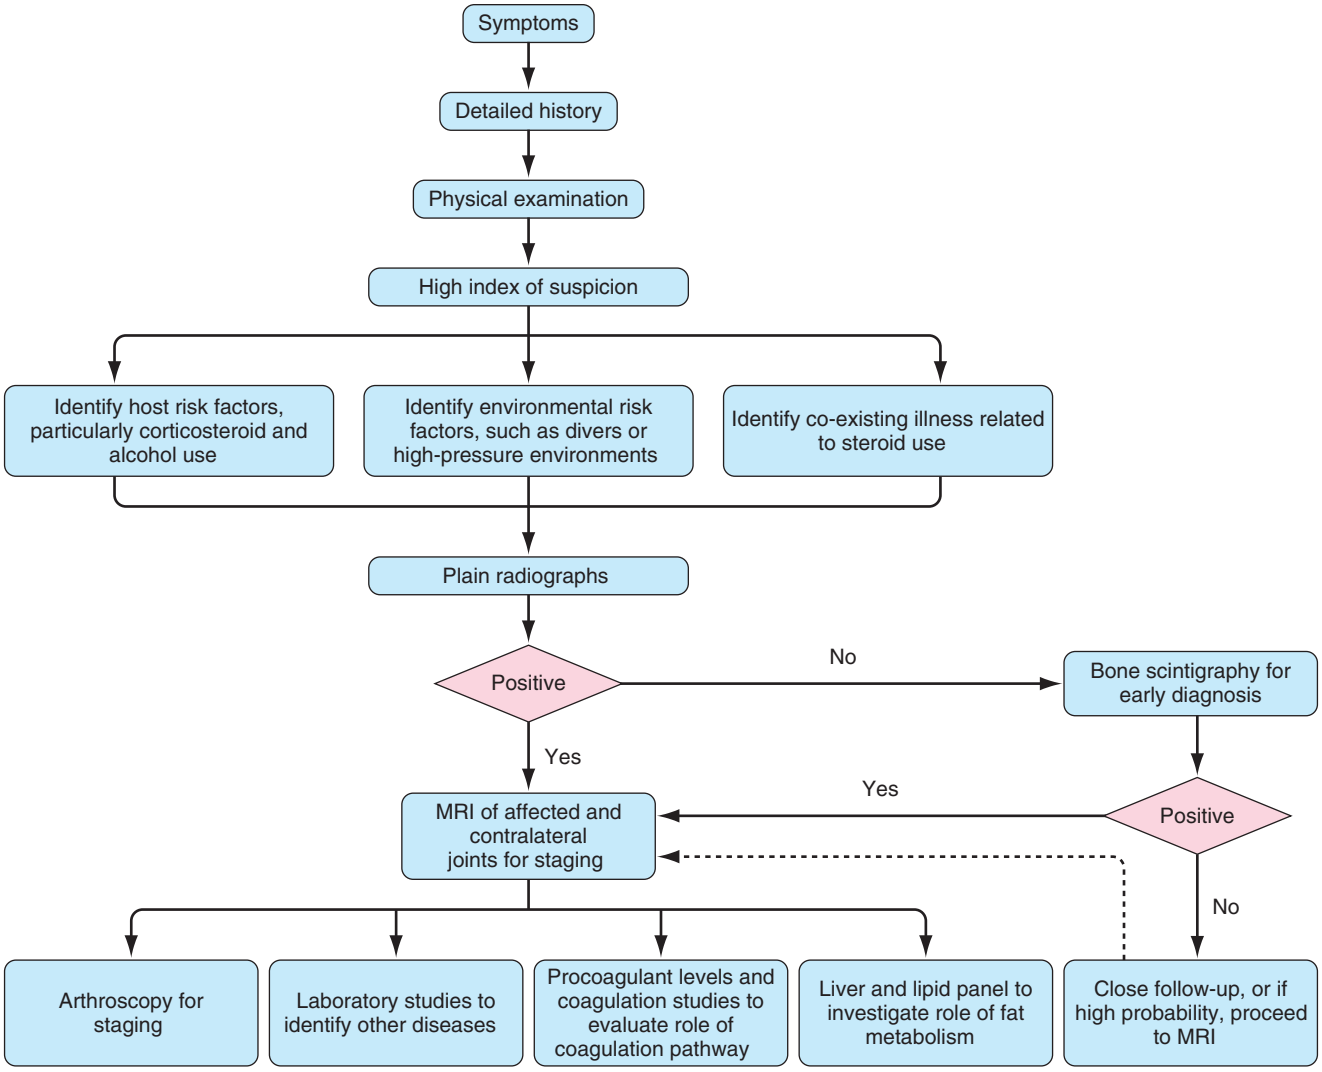

**Figure 103-11** Diagnostic algorithm for osteonecrosis.

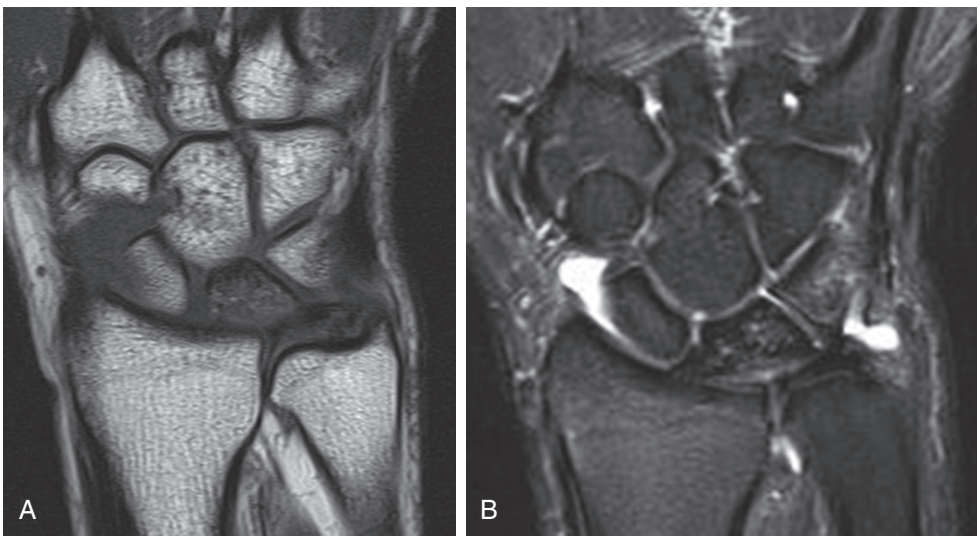

**Figure 103-12** Coronal T1-weighted **(A)** and coronal T2-weighted **(B)** MRI scans of the wrist of a patient with Kienböck's disease. Note the low signal intensity of the lunate in both pulse sequences without bone collapse, indicating the intermediate stage of osteonecrosis of the lunate.

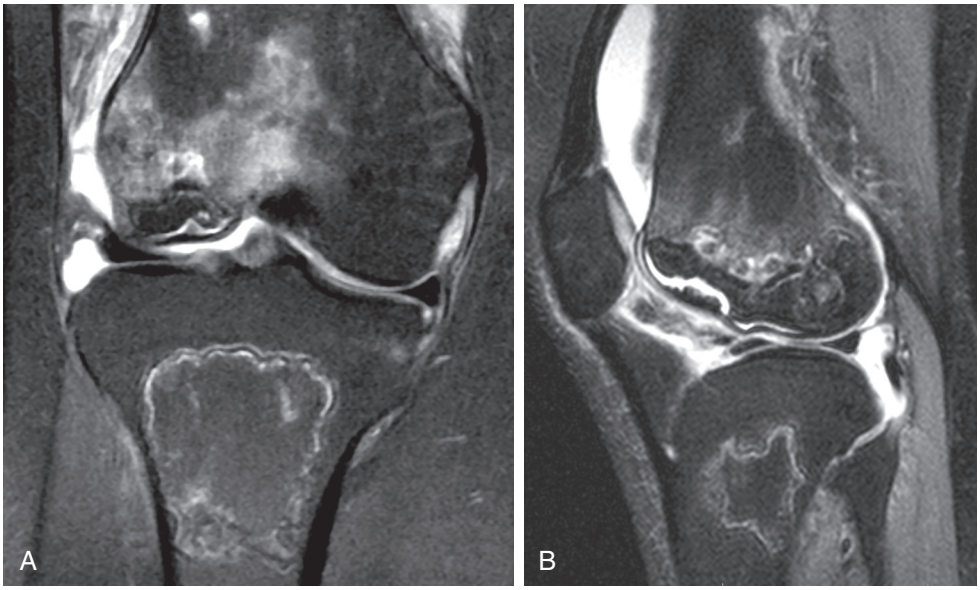

**Figure 103-13** Coronal **(A)** and sagittal **(B)** T2-weighted MRI scans of the knee in a patient with a history of prolonged corticosteroid use demonstrate multiple areas of osteonecrosis of the distal femur and proximal tibia. Note the characteristic double-line sign in the proximal tibial lesion. Note also the partial collapse of the medial femoral condyle as a result of the presence of a subchondral fracture (high signal intensity line in the subchondral bone in **A** and **B**).

Although spontaneous resolution of femoral head osteonecrosis can occur, it is rare and occurs only when the lesion size is small. A study of the prognosis of osteonecrosis of the femoral head as a function of symptoms (pain) and radiographic findings showed that in patients who were asymptomatic and had normal radiographs, progression of the disease was slow, with only 1 of 23 hips progressing to pain and radiographic changes after 5 years. When radiographic changes are already present, disease progresses to pain in 14 of 19 patients after 5 years. In a study of stage 1 osteonecrotic lesions of the hip diagnosed with MRI, 40 patients were followed up for an average of 11 years. All patients had stage 1 lesions on the contralateral hip. Overall, 35 of the 40 stage 1 hips became symptomatic, and 29 hips showed collapse. The mean interval between diagnosis and collapse was 92 months, whereas the mean interval between symptoms and diagnosis was 80 months. Most stage 1 hips eventually progress to a more advanced stage, requiring surgery, and thus these hips should be monitored closely.

## TREATMENT

### Surgery

Most cases of osteonecrosis ultimately require surgical intervention. Sometimes surgical procedures can be used in conjunction with nonsurgical approaches, as will be discussed. The more advanced the disease, the more extensive the surgery that is required.

The various surgical procedures used in the treatment of osteonecrosis include core decompression, structural bone grafting, vascularized fibula grafting, osteotomy, resurfacing arthroplasty, hemiarthroplasty, and total hip replacement. Table 103-8 shows the typical success rates for each of these procedures.

Arthroscopy is a valuable tool used in the treatment of osteonecrosis. It has been used to determine the position of the core decompression tract to the necrotic part of the femoral or humeral head,[165] and arthroscopic débridement has been used in the treatment of osteonecrosis of the capitellum of the humerus in adolescents, in individuals with Kienböck's disease, and in individuals with osteonecrosis of the scaphoid.

Core decompression, which involves the removal of a core of bone from the femoral neck and head, is indicated in less advanced stages of osteonecrosis (Figure 103-14). The core acts as a vent to reduce intraosseous pressure and intramedullary pressure, reversing ischemia and improving symptoms. Other benefits of core decompression include stimulation of angiogenesis, which leads to improved vascularization during the repair process. The effectiveness of core decompression in the treatment of nontraumatic osteonecrosis was illustrated in 34 patients with 54 affected hips. The mean age at presentation was 38 years. The patients were monitored for a mean duration of 120 months after surgery. Success was defined as absence of symptoms, no further progression of disease, and no further surgery. Clinical improvement was established in 26 hips (48%), and radiographic success was established in 20 hips (37%).

Computer-assisted core decompression has been used to provide greater precision in directing the core into the ischemic area and to minimize the duration of radiation exposure to patients.[166] Because early diagnosis improves outcome and the incidence of developing osteonecrosis in a contralateral hip is high, core decompression is frequently performed on both hips simultaneously. This approach adds little risk compared with unilateral core decompression, with the benefit of better outcomes as a result of early surgical treatment of the contralateral hip.[167]

In structural bone grafting, or bone impaction grafting, the bone graft is inserted into the necrotic segment through the core tract. The bone graft acts in similar fashion to a stent, providing support to overlying subchondral bone. The goal is to prevent collapse. This combination of

**TABLE 103-8** Surgical Treatment of Osteonecrosis

| Surgical Procedure | Rationale | Stages of Osteonecrosis | Outcome | Comments |
|---|---|---|---|---|
| Core decompression | Reduction of intraosseous and intramedullary pressure | Early stages | 37% radiographic success, 48% clinical success | Success rate depends on disease stage |
| Structural bone grafting | Provide support to overlying subchondral bone | 1 or 2 | Poor in advanced disease | 100% failure rate in stages 3 and 4 |
| Vascularized fibula grafting | Increase blood flow to graft | 2 to 4 | 96% success in stage 2, 90% in stage 3, and 57% in stage 4 | |
| Osteotomy | Shifting position of osteonecrotic segment out of weight-bearing region | 2 and 3 | Not available | |
| Resurfacing arthroplasty | Preservation of bone and joint mechanics with a metallic or ceramic shell over the femoral head | Later stages | Mean 7-year success rate is 90% | An alternative to total hip arthroscopy in later stages of disease |
| Hemiarthroplasty | Replacement of the femoral head, preservation of the anatomic acetabulum | Later stages | The failure rate for unilateral hemiarthroplasties is 50%-60% at 3 years; for bilateral hemiarthroplasties, the failure rate is 44% | Various techniques are available, some with a better outcome |
| Total hip replacement | Complete replacement of the hip joint | Late stages | 17.4% required revision after 10 years | Eventually most patients will require several hip replacements |

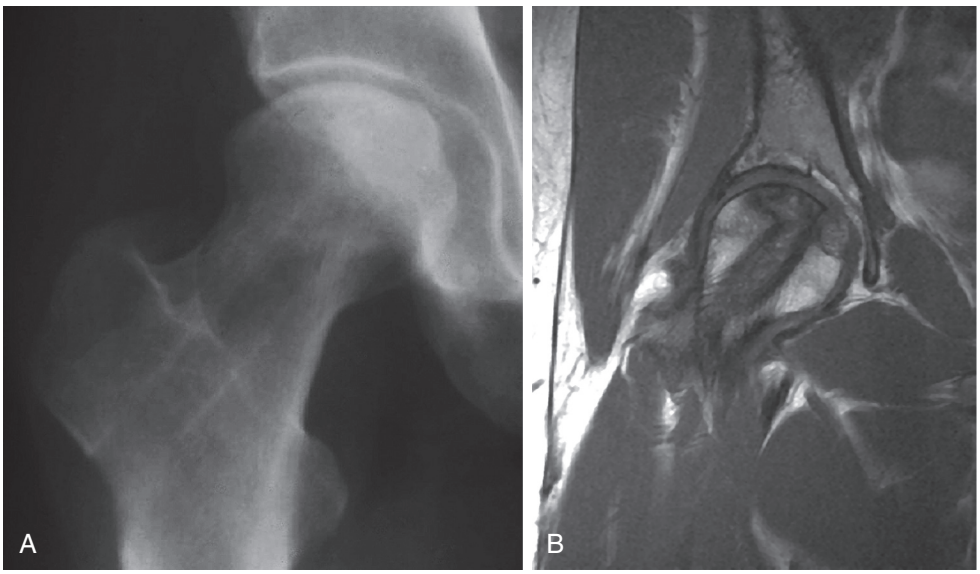

**Figure 103-14** An anteroposterior radiograph **(A)** and a T1-weighted MRI scan **(B)** in a patient who underwent core decompression demonstrate the decompression tunnel extending from the subtrochanteric area into the area of the osteonecrosis in the femoral head.

procedures is frequently used in treating stage 1 or 2 osteonecrotic femoral heads. Allogeneic and autologous bone grafts, mostly harvested from the tibia or fibula, are used. When this technique was attempted in patients with stages 3 and 4 lesions, the outcome was generally poor (100% failure after 2 to 4 years), with progression to collapse and further surgical procedures.[168] Another study investigated outcomes after structural augmentation with autogenous bone grafts in stage 1 and 2 disease in 31 patients (33 hips); all patients had significantly reduced pain, along with an improvement in Harris hip scores from 76 before surgery to 91 after surgery.[169]

Vascularized structural bone grafting also uses the core tract to insert a corticocancellous bone graft into the femoral neck and head along with its vascular pedicle. The vascular pedicle is anastomosed to a nearby vessel, adding a source of blood to the graft. The results of vascularized fibular grafting in the treatment of hips with osteonecrosis showed a survival of 61% of hips at 5-year follow-up and 42% at a median of 8 years.[170] In another study, 197 patients with 226 osteonecrotic hips were treated with a combination of autologous cancellous bone impaction and pedicled iliac bone block transfer. The anastomosis was to the ascending branch of the lateral femoral circumflex artery. Fourteen

hips required conversion to total hip arthroplasty because of collapse, severe pain, or both. Of the remaining 212 hips, 92% were considered a clinical success and 76% were considered radiographically successful. The success rate declined from stage 2 to stage 4 hips (96% for stage 2 hips, 90% for stage 3 hips, and 57% for stage 4 hips).[171] Free vascularized fibula grafting has been compared favorably with other modes of surgical treatment.[172]

Osteotomy of the femur involves shifting the position of the osteonecrotic segment by making a cut in the proximal femur so that the osteonecrotic segment is rotated or flexed out of the weight-bearing region of the acetabulum and then replacing the weight-bearing region with viable bone. Healing of the necrotic region can proceed without the stress of weight bearing. Several different osteotomy techniques have been attempted to salvage hips with stage 2 or 3 osteonecrosis.

Resurfacing arthroplasty uses a metallic or ceramic shell placed over a femoral head that has been débrided of the necrotic area. The potential advantages of resurfacing arthroplasty include preservation of joint mechanics, bone conservation,[173] more physiologic loading of the bone, a lower incidence of perioperative complications, and easier conversion to total hip arthroplasty in case of failure.[174] Complications of this procedure include femoral neck fractures, a secondary osteonecrosis when the procedure is performed for other reasons,[175] and increased metal ion levels.[176] Resurfacing arthroplasty has been recommended for patients with later-stage osteonecrosis, including those with femoral head collapse.[177] A retrospective study compared the results of limited femoral head resurfacing and total hip arthroplasty in 30 consecutive patients with Steinberg stage 3 or 4 disease. The survival rate at a 7-year mean follow-up period for the resurfacing group was 90%, whereas the survival rate at a mean 8-year follow-up for the total hip arthroplasty group was 93%.[178] A recent level 3 therapeutic study showed that hip resurfacing success rates at a 5-year follow-up were comparable with those of total hip arthroplasty in patients with osteonecrosis who were younger than 25 years.[179]

In hemiarthroplasty, only part of the hip joint is replaced. The original acetabulum is preserved, but the femoral head is replaced with a prosthesis. Two types of prostheses are used—a unipolar prosthesis and a bipolar prosthesis. In a unipolar prosthesis, the articulation is between the artificial femoral head and the acetabulum. In the bipolar prosthesis (presently the most frequently used), the articulation is within the prosthesis itself. Failure rates for hemiarthroplasties in individuals with osteonecrosis are 50% to 60% at 3 years for unipolar prostheses and 44% for bipolar prostheses. Another study evaluated the success rate of Charnley/Bicentric hemiarthroplasty in the treatment of Ficat and Arlet stage 3 osteonecrosis of the femoral head. Failures included three hips that needed to be revised to cementless total hip replacement, two hips with radiographic changes of loosening and imminent failure, and one hip with progressive loss of joint space and secondary degenerative changes. The success rate was 84.2% after a mean of 56 months.

Total hip arthroplasty is complete replacement of the hip joint with a prosthesis, including the femoral head and the acetabulum. In a study of 55 consecutive hip arthroplasty procedures, cementless total hip arthroplasty was shown to provide favorable results in advanced-stage osteonecrosis of the femoral head. Although 10 of the 48 hips available for follow-up after a minimum of 5 years required revision, all of these patients had Ficat and Arlet stage 3 or 4 disease. A study of 53 hips in 41 patients treated with cemented total hip replacement showed that at a minimum of 10 years of follow-up, 17.4% required revision. Compared with cemented total hip replacements performed for other conditions, osteonecrosis had a greater risk for loosening of acetabular and femoral components. A survivorship analysis of cemented total hip replacements in renal transplant patients with osteonecrosis of the femoral head showed excellent survival after 10 years (98.8%). After 20 years, the survival rate decreased to 63.8%.

In individuals with ONJ, the most common surgical procedure is resection of the affected bone.[180] Conservative treatment has also been used but has a higher recurrence rate. A larger extent of surgical excision and a higher number of surgical débridements were associated with a lower recurrence rate. Other modes of surgical therapy for ONJ include bone-contouring procedures, fluorescence-guided bone-contouring procedures,[181] and segmental osteotomies, but these procedures are generally reserved for more severe cases. Nonsurgical treatments, including hyperbaric oxygen therapy[182] and low-intensity laser therapy, are controversial but have been used to treat ONJ.

## Nonsurgical Approaches

The key to the successful treatment of osteonecrosis is early detection. Because many patients with osteonecrosis are relatively young, and because treatment of late-stage osteonecrosis is associated with high failure rates, earlier detection may be associated with a greater chance of preservation of the hip. The choice of conservative nonsurgical versus more aggressive surgical options depends on the clinical and pathologic staging of the disease. Figure 103-15 is an algorithm for the treatment of osteonecrosis.

Nonsurgical treatment of osteonecrosis of the femoral head includes refraining from weight bearing on the affected joint, use of analgesic and anti-inflammatory medications, and physiotherapy. Conservative medical treatment is effective only in the early stages for symptomatic relief. Nonsurgical management does not seem to alter the natural course of the disease. Electrical stimulation has been used in the treatment of osteonecrosis, in conjunction with core decompression. Electrical stimulation enhances osteogenesis and neovascularization. It also alters the balance between osteoblast and osteoclast activity, resulting in increased bone deposition and decreased bone resorption. Delivery of electrical stimulation can be performed by direct current (DC), pulsed electromagnetic field, and capacitance coupling. The success of electrical stimulation in the treatment of osteonecrosis has been rather mediocre. A study was performed of 11 hips in 8 patients with Ficat stage 2 osteonecrosis who underwent core decompression and placement of an electric stimulating coil within the core in the anterosuperior segment of the femoral head.[183] Of these 11 hips, 5 required a repeat operation, and 6 had progressive deterioration 13 months after initial placement of the coil. In addition, there was little histologic evidence that the coil did indeed

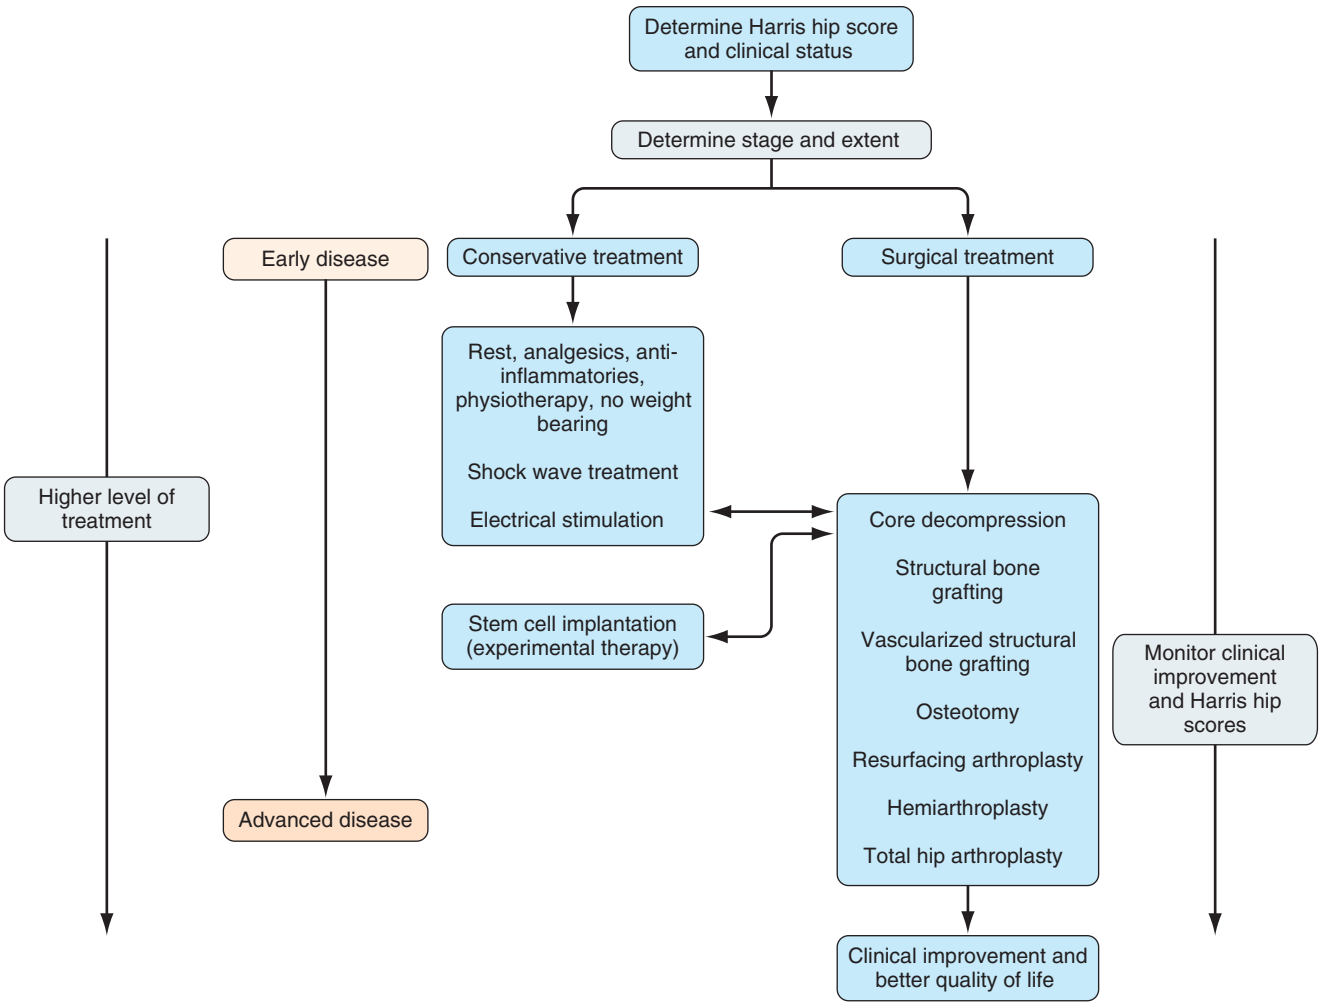

**Figure 103-15** Treatment algorithm for osteonecrosis.

generate new bone deposition around itself. The efficacy of this method of treatment is unproven.

On the other hand, another study compared the effectiveness of conservative nonsurgical treatment with core decompression with or without DC electrical stimulation.[184] The clinical symptom scores and the rate of progression to arthroplasty were best in the group with core decompression and DC electrical stimulation and worst in the nonoperative group. Capacitive coupling can be performed with or without core decompression and grafting. Forty patients with stage 1 to 3 osteonecrosis underwent core decompression and grafting; half of the patients wore active capacitive coupling units with electrodes over the femoral head for 6 months. The control group was 55 patients with osteonecrosis who were treated conservatively. Follow-ups at 2 and 4 years showed that core decompression with or without capacitive coupling provided a better clinical and radiologic outcome than did conservative treatment. Capacitive coupling did not improve the results further when used with core decompression and grafting.

Extracorporeal shock wave therapy has been used in the treatment of osteonecrosis of the femoral head. A study of 48 patients and 57 hips compared extracorporeal shock wave therapy with core decompression and bone grafting. Twenty-three patients with 29 affected hips were assigned to the shock wave group, and the remaining patients and hips were treated surgically. The patients in the shock wave group were given treatment of 6000 pulses of shock waves at 28 kV to the affected hip. The patients were evaluated radiographically and by their reports of symptoms (pain), Harris hip scores, and quality of life (daily work activity assessment). Shock wave therapy produced better results than did the nonvascularized bone grafting procedure, with comparatively less progression of disease.[185] In 35 patients with 47 osteonecrotic hips, the use of shock wave therapy led to improvements in serum nitric oxide levels, angiogenic factors such as VEGF, and osteogenic factors such as bone morphogenetic protein (BMP)-2 and osteocalcin. Levels of inflammatory markers were reduced. It is interesting to note that although these changes did not persist beyond several months, the clinical and radiographic improvement, present in 83% of hips, was present after 12 months.[186]

Conservative treatment of osteonecrosis of the talus is not promising, and the affected ankles generally continue to progress, requiring either core decompression or arthrodesis. Conservative treatment of bisphosphonate-induced ONJ includes cessation of bisphosphonate usage or surgical

débridement. Good oral hygiene, regular dental assessment, and avoidance of dental procedures during bisphosphonate usage can prevent the onset of osteonecrosis.

## RECENT DEVELOPMENTS

### Prevention Versus Treatment

A recent study evaluated the role of antioxidants in the treatment of osteonecrosis. Japanese white rabbits were divided into two groups and fed either a normal diet or a normal diet supplemented with α-tocopherol. Osteonecrosis developed in 14 of 20 rabbits in the control group but in only 5 of 21 rabbits in the experimental group. This finding suggests that oxidative stress may play a role in the pathogenesis of osteonecrosis and that a role may exist for antioxidants such as vitamin E.[187]

A group of researchers studied the use of adrenocorticotropic hormone (ACTH) in rabbits to prevent corticosteroid-induced osteonecrosis and found that if ACTH is administered along with depot methylprednisolone acetate (Depo-Medrol), osteonecrosis is reduced. The authors of this study believe that ACTH enhances osteoblast support and stimulates the production of VEGF, which stimulates the generation of new blood vessels. The result is an increase in blood flow to the vulnerable areas of bone, preventing cell death and reducing the likelihood of osteonecrosis.[188]

### Mesenchymal Stem Cells

Corticosteroids interfere with the balance of adipogenesis and osteogenesis in the differentiation of mesenchymal stem cells. Corticosteroids shunt uncommitted osteoprogenitor cells in the bone marrow into the adipocytic pathway, leading to reduced osteoblast formation. Corticosteroids have also been shown to reduce VEGF, which leads to a reduction in new blood vessel formation and potentially can lead to bone death. Alcohol has a similar effect on the differentiation of progenitor cells.

The balance between adipogenesis and osteogenesis has been targeted as a potential site for the treatment of osteonecrosis. Multipotential mesenchymal stem cells from femoral bone marrow near osteonecrosis sites are able to express messenger RNA aggrecan and type II collagen. Both are deposited into the bone matrix. These features are characteristic of chondrogenic differentiation. The mesenchymal stem cells can be differentiated into osteocytic lineage in vitro.

A pilot study evaluating the effectiveness of implantation of autologous bone marrow cells in the treatment of osteonecrosis used core decompression to implant stem cells into the necrotic lesions of the femoral head. The patients were divided into two groups—one that received core decompression alone as treatment for osteonecrosis (the control group) and one that received autologous bone marrow cell implantation along with core decompression (the treatment group). The patients were followed up for 24 months, and at that time, 5 of 8 hips in the control group, but only 1 of 10 in the treatment group, advanced to stage 3 osteonecrosis. In addition, greater improvement in pain and joint symptoms occurred in the treatment group, and the treatment seemed to be safe. Because of the small number of patients involved, further studies are necessary to confirm these results.

Twenty-eight patients with 44 necrotic hips were treated with percutaneous decompression and autologous bone marrow mononuclear cell infusion. Patients were followed up for a minimum of 2 years and evaluated for clinical and radiographic progression of the disease. Overall slowing in the progression of the disease stage appeared to occur. The mean Harris hip score improved from 58 to 86.

In 2014, Houdek and colleagues[189] reviewed the literature and published a report in which they concluded that using core decompression in conjunction with mesenchymal stem cell infusion in the form of bone marrow leads to improved pain and functionality and halts progression of osteonecrosis of the femoral head, potentially obviating the need for future invasive procedures such as total hip replacement.[189]

## CONCLUSION

Osteonecrosis is a potentially debilitating condition with significant morbidity despite medical interventions or surgery. Corticosteroid use is the most common cause of osteonecrosis, and corticosteroid-induced osteonecrosis can be reproduced in animal models. The pathogenesis of osteonecrosis is multifaceted and is still not completely understood. Why is it that corticosteroid-induced osteonecrosis is more common in patients with certain underlying diseases and not in others? Does osteonecrosis have a genetic or epigenetic basis, and is there a familial predisposition? Common pathogenic mechanisms known to be involved in osteonecrosis include osteoblast/osteoclast survival and apoptosis, lipid metabolism, and coagulation abnormalities. However, it is still unclear how these mechanisms interrelate. To better appreciate the risk factors involved in osteonecrosis, a more complete understanding of the pathogenesis is necessary. Until then, the physician should always maintain a high index of suspicion for osteonecrosis whenever known risk factors are present, especially use of corticosteroids and alcohol.

CHAPTER 104

# Relapsing Polychondritis

Gaye Cunnane

**KEY POINTS**

- Relapsing polychondritis (RPC) is a rare, systemic autoimmune disorder characterized by episodic inflammation of cartilaginous structures.
- Classic clinical findings include "cauliflower ear" and "saddle nose" deformities.
- RPC may cause significant pathology of the upper airways, eyes, inner ears, kidneys, and blood vessels, with potentially life-threatening consequences.
- The disease may be primary or it may develop in association with other diseases, such as myelodysplasia, vasculitis, or other autoimmune/connective tissue disorders.
- Although there are no specific laboratory markers for RPC, the diagnosis is made by observing the classic clinical features and may be confirmed by the characteristic histologic findings of affected tissues.
- Because of the multisystem nature of the disease, a broad approach to diagnosis and management is essential.
- Treatment is frequently empiric because of the wide variety of disease manifestations and lack of controlled trials. However, immunosuppression is the mainstay of therapy.

Relapsing polychondritis (RPC) is a rare autoimmune disease of unknown etiology, characterized by episodic inflammation of cartilaginous structures throughout the body (e.g., the ears, nose, upper respiratory tract, chest wall, and joints). Noncartilaginous tissues may become involved, particularly those with an abundance of proteoglycans, such as the eye, inner ear, heart, blood vessels, and kidney.[1] Associated diseases such as vasculitis or myelodysplastic syndromes are present in as many as one-third of cases. The severity of the inflammatory process frequently requires the use of immunosuppressive agents. As its name suggests, RPC has an episodic pattern with periods of intense inflammation. Prognosis is variable, with a 5-year survival rate of 45% to 95%, depending on organ involvement and disease or treatment complications.[2]

This disease was first described in 1923 by Rudolf Jaksch von Wartenhorst, an internal medicine physician, when he published the case of a young male with characteristic clinical features and named the disease *polychondropathia*.[1,3] In 1960 Pearson et al. provided a more detailed description, and renamed the disease *relapsing polychondritis*.[4]

## EPIDEMIOLOGY

The worldwide incidence of RPC is unknown, but figures from Rochester, Minnesota, suggest an annual incidence of 3.5 per million in that community.[4] RPC occurs in all racial groups and with similar frequency in men and women. Peak age of onset is 40 to 50 years, but it has been described in children[5] and in people older than 80 years.[6] No familial pattern of inheritance has been shown.[7]

## PATHOLOGY

### Normal Cartilage

There are three types of cartilage tissue (hyaline, elastic, and fibrocartilage), which differ in the composition of the extra-cellular matrix. The cellular component of cartilage consists of chondrocytes, whereas the extra-cellular matrix is composed of interlinking fibrils of type II collagen, other collagens, hydrophilic proteoglycan aggregates, and a variety of matrix proteins.[8] One such protein, matrilin-1, is exclusive to the respiratory tract, ears, and xiphisternum in adults and is only found in articular cartilage before skeletal maturity.[9] Cartilage is an avascular structure that derives essential nutrients from adjacent tissue. The composition of cartilage confers resilience to external compressive forces. In healthy adults, turnover of cartilage components is slow, with incomplete repair processes.[10] Degradation of collagen fibrils occurs with age, resulting from imbalances between naturally occurring proteolytic enzymes and their inhibitors.[11]

### Relapsing Polychondritis Cartilage

There are limited data on the microscopic changes in tissue affected by RPC, partly because of the low disease incidence and also because the diagnosis is usually made on clinical grounds. In the initial stages, inflammatory cells infiltrate the perichondrium, with evidence of lymphocytes ($CD4^+$ T cells), macrophages, neutrophils, eosinophils, and plasma cells on hematoxylin-eosin staining, whereas the structure of the cartilage appears unaffected.[12,13] Immunofluorescence may reveal deposits of immunoglobulin and cartilage components at the cartilage-perichondrium junction.[14] Later, the inflammatory cells invade the cartilage, releasing proteolytic enzymes such as matrix metalloproteinases and cathepsins.[13,15] While the cartilage is destroyed, it loses its

Supplemental images available on the accompanying ExpertConsult website.

basophilic staining, while elastic and collagen fibers become disrupted.[13]

Necrosis and a reduction in cartilage components may be observed. The cartilage is subsequently replaced by fibrotic tissue, with areas of calcification. Granulation tissue and gelatinous cysts may be observed within involved areas.[13]

## PATHOGENESIS

Although the pathogenesis of RPC is unknown, evidence supports the concept of an autoimmune process. The presence of inflammatory cells and immune complexes in involved cartilage, the detection of autoantibodies to cartilage components, the association with human leukocyte antigen (HLA)-DR, the frequent concurrence with other autoimmune diseases, and the response to immunosuppressive treatment all support this hypothesis. Researchers have observed autoantibodies to types II, IX, and XI collagen in patients with this disease,[9,16-18] and autoantibodies to matrilin-1 and cartilage oligomeric protein (COMP) have been detected in patients with respiratory tract involvement.[19-22] Type II collagen neoepitope can be found in the urine of patients with active disease.[23] More recently, the serum level of soluble triggering receptor expressed on myeloid cells-1 has been cited as a potential biomarker of disease activity in RPC.[24] Pro-inflammatory chemokines involved in the recruitment of monocytes and modulation of macrophage function, such as monocyte chemoattractant protein-1, macrophage inflammatory protein 1β, and interleukin (IL)-8, are significantly elevated in active RPC compared with controls.[25] Tumor necrosis factor expression is also higher in RPC.[25] Furthermore, there is a class II HLA association with RPC. A twofold increase in HLA-DR4 has been found in RPC, although a specific subtype has not been identified.[26] There is a negative association between the extent of organ involvement in RPC and HLA-DR6.[27]

Several animal models have helped to elucidate some of the pathogenetic mechanisms underlying RPC. Chondritis can be induced in certain rat or mice species following injection of type II collagen.[28,29] In addition, mice that express HLA-DQ6ab8ab transgenes develop a spontaneous form of polychondritis with auricular, nasal, and joint involvement.[30] Experiments that used the matrilin-1–induced rodent model of RPC have demonstrated the importance of T cells, B cells, and complement components in pathogenesis of this disease.[31] Deletion of IL-10 in this model resulted in increased disease severity, suggesting a role for this endogenous cytokine in suppressing episodic inflammation.[32] The processes involved in the initiation of disease, escalation of the inflammatory response, and subsequent cartilage destruction are poorly understood. In a healthy individual, cartilage is an immunologically privileged site.[9] However, in RPC, cartilage components are exposed and vulnerable to immunologic attack, resulting in a perpetuating process of systemic inflammation and local tissue damage. In genetically susceptible individuals, cartilage microtrauma or molecular mimicry between an infectious/inciting agent and cartilage structures might instigate a cycle of inflammation similar to other autoimmune disorders.[13,33]

## CLINICAL FEATURES

RPC can be diagnosed when the characteristic clinical signs are present. The diagnostic criteria for RPC are outlined in Table 104-1. Because of the relapsing nature and rarity of the disease, the diagnosis may not be established for some time. In one study, a mean delay of 2.9 years was noted between symptom onset and confirmation of diagnosis.[34] Table 104-2 documents the frequency of clinical presentations in patients with RPC.

### Otorhinologic Disease

The most characteristic manifestation of RPC is auricular chondritis, in which the patient develops acute pain, redness, and swelling of the cartilaginous upper two-thirds of the outer ear, sparing the lobe[35] (see supplemental Figure 104-1 on ExpertConsult.com). It may be unilateral or bilateral and resolves spontaneously during a period of several

**TABLE 104-1** Diagnostic Criteria

| |
|---|
| **Major Criteria**<br>Proven inflammatory episodes of ear cartilage |
| Proven inflammatory episodes of nose cartilage |
| Proven inflammatory episodes of laryngotracheal cartilage |
| **Minor Criteria**<br>Eye inflammation |
| Hearing loss |
| Vestibular dysfunction |
| Seronegative inflammatory arthritis<br>• Diagnosis is made by two major criteria or one major plus two minor criteria.<br>• Histologic examination of affected cartilage is not required. |

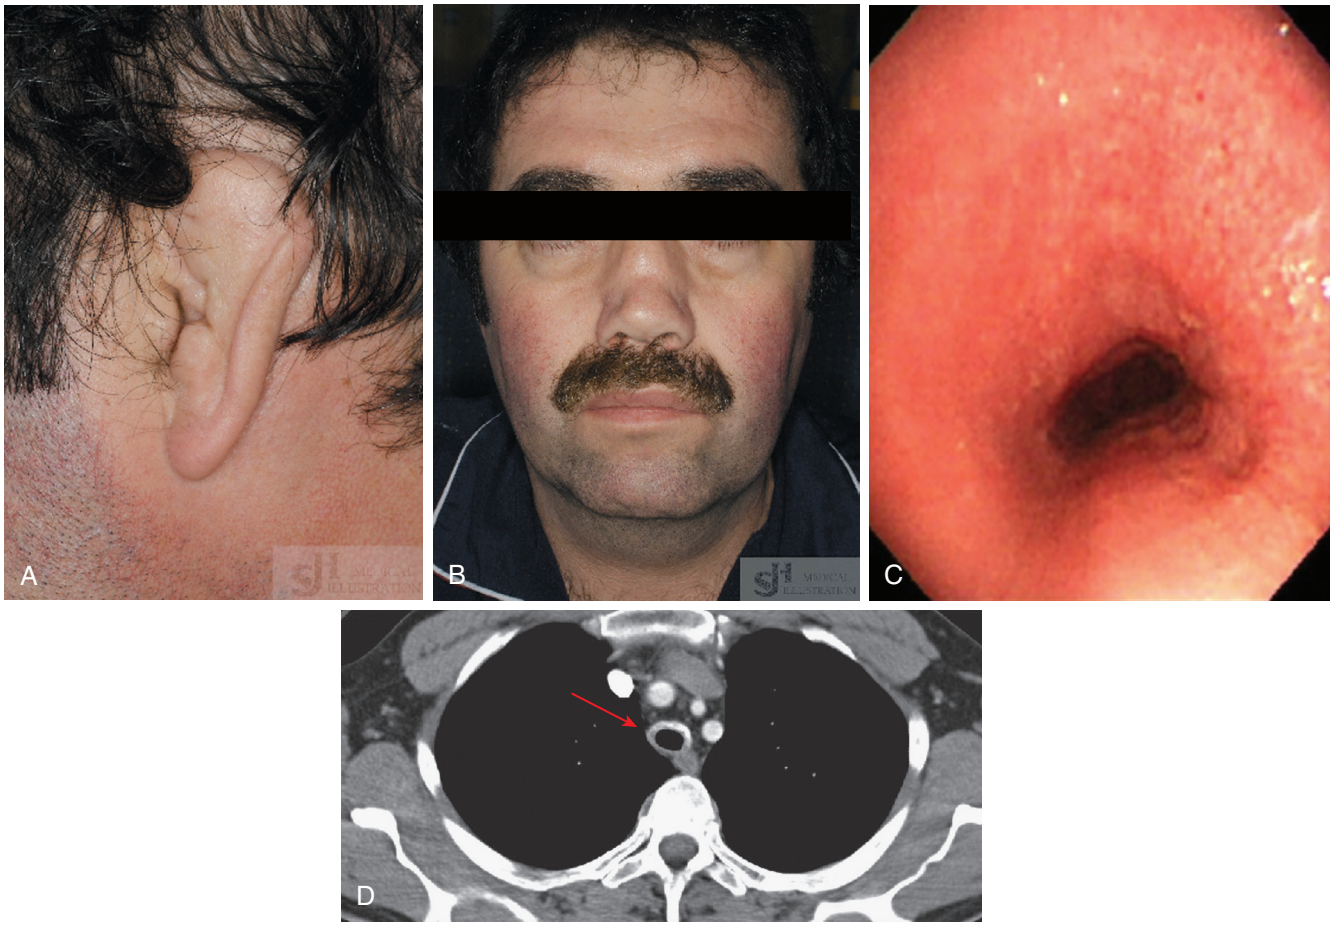

**Figure 104-1** **A,** Chronic changes of relapsing polychondritis (RPC) in the cartilaginous upper two-thirds of the ear, evident after repeated episodes of inflammation in this area. **B,** Saddle nose deformity, developed after episodic nasal chondritis. **C,** Bronchoscopy findings demonstrating mucosal hyperemia, edema with lack of normal detail of tracheal cartilaginous rings, and flattening of the trachea. **D,** Computed tomography thorax with *arrow* demonstrating tracheal flattening and calcification in a patient with RPC. *(**A** and **B,** Courtesy Mr. Anthony Edwards, Clinical Photographer, St. James's Hospital, Dublin, Ireland. **C** and **D,** Courtesy Dr. Finbarr O'Connell, Consultant Pulmonologist, St. James's Hospital, Dublin, Ireland.)*

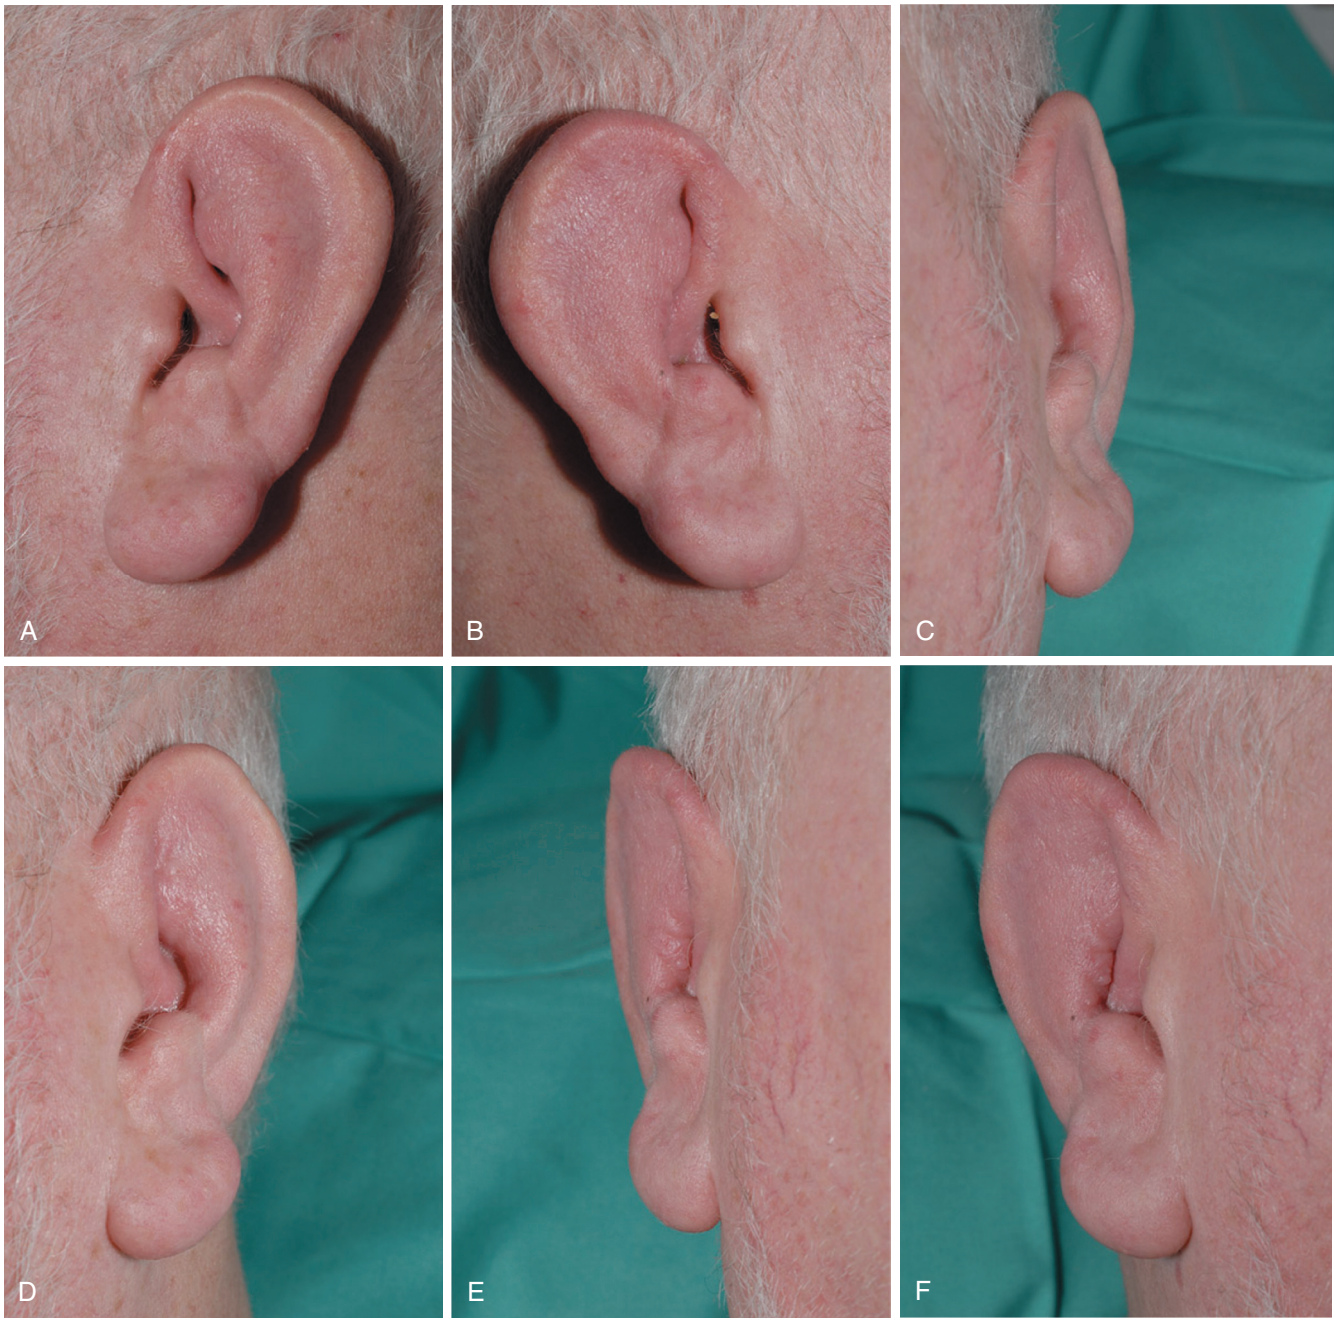

weeks. Repeated episodes result in visible damage to the ear, which takes on a deformed, flaccid appearance (Figures 104-1A and 104-2). Although classic for RPC, this is the presenting feature in only 40% of patients, although this feature eventually develops in as many as 85% of patients during the course of their disease.[6] Such swelling of the outer ear causes temporary conductive deafness. However, sensorineural deafness may result from an associated vasculitis of the internal auditory artery or its branches, leading to additional vertigo in some patients.[34,35] Nasal chondritis develops in approximately 10% of patients at presentation and as many as 70% during the course of their disease.[6,35] Repeated inflammatory episodes result in collapse of the nasal bridge and an alteration of the facial appearance—the so-called *saddle-nose* deformity (Figure 104-1B).

## Respiratory Disease

Involvement of the upper respiratory tract may be life threatening and should be investigated at an early stage in the disease course. Approximately 50% of patients with RPC develop respiratory problems, which are associated with a worse prognosis.[36] Hoarseness, dysphonia, a persistent dry cough, or anterior neck tenderness may indicate laryngeal or tracheal disease. Inflammation of the tracheobronchial tree may lead to tracheomalacia, dynamic obstruction, and acute respiratory failure, whereas repeated inflammatory episodes cause subglottic stenosis, chronic dyspnea, and increased susceptibility to infection.[37,22] Obstruction may be precipitated by attempts at intubation or bronchoscopy.[34] Computed tomography and bronchoscopy appearances of one patient with RPC are demonstrated in Figure 104-1C and D. The development of costochondritis may result in chest pain, leading to additional respiratory symptomatology.

## Cardiovascular Disease

Large and small vessel disease can occur during the course of RPC in as many as 10% of cases.[38] Such complications typically develop in patients with well-established disease, even in the setting of immunosuppression.[38-41] Inflammation of the aorta, most likely to occur at the level of the root or arch, leads to aneurysm formation and aortic incompetence, which may develop acutely with minimal prior symptoms.[34,40] Valvular problems are more common in

**Supplemental Figure 104-1** **A-F,** This series of photographs depicts the ear of a 56-year-old man with relapsing polychondritis. His disease was uncontrolled for 1 year, during which the damage shown developed in the cartilaginous structures of the ear.

**Figure 104-2** Acute on chronic changes of relapsing polychondritis in the cartilaginous upper two-thirds of the ear. *(Courtesy Professor Iain McInnes, Glasgow, United Kingdom.)*

males.[41] Aortic valve disease may be to the result of progressive dilatation of the aortic ring rather than active local inflammation.[34] Mitral regurgitation may result from valvitis or papillary muscle involvement.[34] Furthermore, myocarditis may lead to cardiac failure and conduction system abnormalities.[34,38] Small vessel vasculitis has also been reported and may cause end-organ damage to the skin, kidneys, testes, sclera, cochleovestibular system, or other areas.[34,38,42]Arterial and venous thromboses have been described in association with RPC.[34]

### Eye Disease

As many as 65% of patients with RPC will develop ocular disease, most commonly episcleritis and scleritis.[2] Recurrent inflammation can lead to thinning of the sclera, giving a bluish appearance to the eye.[1] Keratoconjunctivitis sicca may occur with associated Sjögren's syndrome. Uveitis, retinal vasculitis, and optic neuritis are rare complications. Extraocular muscle palsy, periorbital edema, and proptosis may also occur as part of the RPC symptom complex.[2]

### Renal Disease

Proteinuria and/or hematuria may be observed on urinalysis in approximately 10% of patients with RPC.[43] Renal pathology has been reported to show mesangial proliferation and segmental necrotizing crescentic glomerulonephritis.[43] Electron microscopy may demonstrate immunoglobulin and complement deposits. Renal pathology may also occur in the context of co-existing diseases such as systemic lupus erythematosus or other rheumatic diseases. Patients with RPC and renal involvement have a greater incidence of associated vasculitis and a resultant worse prognosis.[43]

### Neurologic Disease

Central and peripheral nervous system involvement is rare, affecting up to 10% of patients.[27] Cranial neuropathy is the most common manifestation, but a wide variety of problems including headache, ataxia, hemiplegia, transverse myelitis, mononeuritis multiplex, aseptic meningitis, and encephalopathy have been described. Such lesions may be vasculitic or autoimmune in nature.[35,42,44]

### Mucocutaneous

Skin and mucous membrane changes develop in approximately 50% of patients with RPC. Rashes are present in as many as 35% of patients with primary RPC, whereas 90% of patients with associated myelodysplasia have mucocutaneous involvement.[45] Oral aphthous ulcers are the most common symptom. Peripheral nodules, similar to erythema nodosum, can be noted in approximately 15% of patients.[45] Rare skin lesions include peripheral limb ulcers, livedo reticularis, panniculitis, superficial thrombophlebitis, urticaria, and angioedema. Leukocytoclastic vasculitis, dermal vessel thrombosis, or septal panniculitis may be evident on biopsy.[45]

### Joint Disease

Musculoskeletal manifestations are common and develop in 75% of patients during the course of the disease.[35] Involvement of the joints may be oligoarticular or polyarticular, most commonly affecting the ankles, wrists, hands, and feet. Recurring pain in the sternoclavicular, costochondral and manubriosternal joints has been described.[1] However, other joints, including the sacroiliac joints, may also show evidence of inflammation, although it is possible that the presence of sacroiliitis relates to the co-existence of a spondyloarthropathy.[46] The arthritis associated with RPC is typically asymmetric, episodic, and nonerosive, and it does not correlate with activity of RPC.[35]

## ASSOCIATED DISORDERS

RPC has been described in association with a variety of other disorders, including rheumatic, vasculitic, and hematologic syndromes. Its co-existence with Behçet's disease has led to the acronym *MAGIC* syndrome: mouth and genital ulcers with inflamed cartilage.[47] In older patients, RPC may be associated with myelodysplasia and a worse prognosis[48,49] (Table 104-3).

## DIFFERENTIAL DIAGNOSIS

Auricular chondritis with sparing of the earlobe is characteristic of RPC. Redness and swelling of the whole ear, including the earlobe, may be the result of trauma or exposure to temperature extremes and should be distinguished from RPC. *Pseudomonas aeruginosa* or *Staphylococcus aureus* are potential causes of unilateral otitis externa, particularly in immunocompromised patients.[50] Other

Modified from Trentham DE, Le CH: Relapsing polychondritis. *Ann Intern Med* 129:114–122, 1998; and Francès C, el Rassi R, Laporte JL, et al: Dermatologic manifestations of relapsing polychondritis. A study of 200 cases at a single center. *Medicine (Baltimore)* 80:173–179, 2001.

infections associated with chondritis include leprosy and syphilis. Damage to the nose cartilage may be to the result of trauma, local infections, or granulomatous lesions such as anti-neutrophil cytoplasmic antibody (ANCA)-associated granulomatosis vasculitis or lethal midline granuloma. Intranasal cocaine use should also be considered. A wide variety of inflammatory, rheumatic, and infectious conditions may mimic some features of RPC, particularly when multiple organs are involved. Cogan syndrome is an inflammatory autoimmune condition that results in keratitis and vestibuloauditory symptoms and may be associated with vascular inflammation, although it is not linked with chondritis.[51] Causes of systemic vasculitis (e.g., ANCA-associated vasculitis, polyarteritis nodosa, Behçet's disease, rheumatoid arthritis, or those associated with connective tissue disorders) should be taken into consideration, especially when the presentation is atypical. Valvular heart disease, particularly aortic incompetence and aortic root dilatation, may occur in conditions such as Marfan syndrome, syphilis, and idiopathic medial cystic necrosis and can also develop in relation to diseases that may coincide with RPC (e.g., ankylosing spondylitis).

## INVESTIGATIONS

### Routine Laboratory Tests

Routine laboratory tests should be performed and may demonstrate nonspecific findings such as anemia or mild thrombocytosis. The acute phase response is typically elevated during periods of inflammation. Urinalysis should always be performed to determine the presence of subclinical renal disease or infection. Autoimmune tests are nonspecific, except when associated diseases are present concurrently.

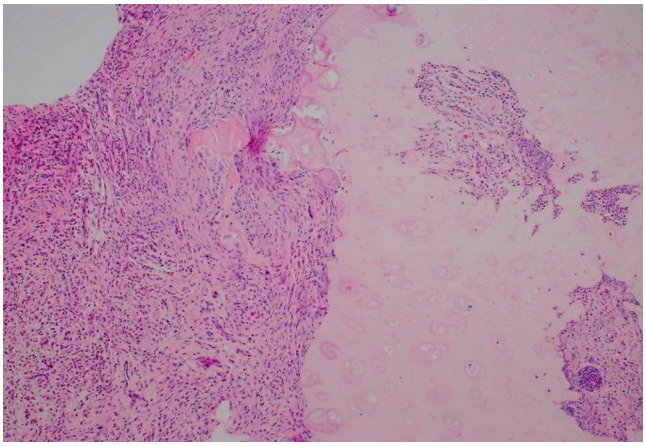

**Figure 104-3** Histopathology of tracheal biopsy of a 75-year-old man who presented with vocal cord palsy. Hematoxylin and eosin staining demonstrates a marked inflammatory response invading into cartilage. *(Courtesy Drs. Mary Toner and Mairin McMenamin, Department of Pathology, and Mr. John Kinsella, Department of Ear, Nose, and Throat, St. James's Hospital, Dublin, Ireland.)*

### Tissue Sampling/Histopathology

In typical presentations of RPC, a biopsy is not necessary for diagnosis. However, when the diagnosis is unclear, a biopsy of inflamed cartilage may show evidence of perichondritis, as described earlier (Figure 104-3).[9,34] Skin rashes may demonstrate leukocytoclastic vasculitis; other frequent findings include panniculitis, neutrophilic dermatoses, or dermal vessel occlusion.[45]

### Pulmonary Studies

Clinicians should conduct pulmonary function tests in all suspected cases of RPC, even in patients who are asymptomatic at presentation. These tests (including spirometry, lung volumes, and inspiratory/expiratory flow-volume loops) should be repeated in the event of new respiratory symptoms. If the test results are abnormal, computed tomography (CT) of the chest is recommended to detect the presence of tracheal or bronchial stenoses or dynamic airway collapse, which may be evident only during the expiratory phase of the respiratory cycle.[52-54] Extrapulmonary disease from costochondritis may cause a restrictive pattern on pulmonary function testing. Positron emission tomography/CT (PET/CT) scanning may have additional value because it can identify the presence of inflammation in areas where it is otherwise undetectable. PET/CT can also demonstrate treatment response with a reduction in inflammation after therapeutic intervention[55-57] (Figure 104-4).

Bronchoscopy is warranted only if specifically indicated because the procedure may cause inadvertent damage to the upper airways, with the risk of precipitating respiratory failure. However, indirect laryngoscopy is helpful to monitor airway involvement. Bronchoscopic ultrasound can also be used to monitor disease.[58]

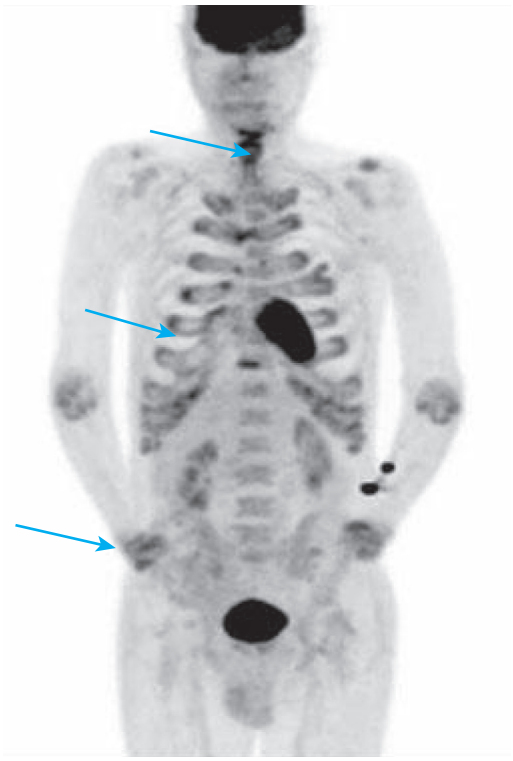

**Figure 104-4** Positron emission tomography/computed tomography scan image of a patient with relapsing polychondritis. Uptake of fluorodeoxyglucose can be seen in the trachea, costal cartilages and upper limb joints *(arrows)*. *(From Czepczyński R, Guzikowska-Ruszkowska I, Wyszomirska A: Relapsing polychondritis detected by PET/CT.* Eur J Nucl Med Mol Imaging *39:1366–1367, 2012. Courtesy of Springer.)*

### Cardiac Studies

Echocardiography is necessary to evaluate the aortic root and heart valves. Furthermore, many systemic inflammatory diseases are associated with accelerated atherosclerosis, and this may also be true for patients with RPC, although because of small numbers of cases, this has not been widely described. Nevertheless, other cardiac disease risk factors should be ascertained.

### Ophthalmologic Studies

Routine retinoscopy should be performed at diagnosis. Referral to a specialist unit is recommended if abnormalities are detected and/or if symptoms develop.

### Imaging

Plain radiographs of involved joints may show joint space narrowing or periarticular osteopenia. Erosions are not observed, unless there is an associated rheumatic disorder. Dual x-ray absorptiometry may demonstrate osteopenia as a consequence of the underlying inflammation or general debility.

### Additional Studies

At present, genetic testing offers little added benefit. Serum levels of cartilage biomarkers such as COMP or indications of an immune response to cartilage (e.g., antibodies to types II, IX, or XI collagen or matrilyin-1) are not routinely available, and their role in disease activity monitoring is unclear.[20,22,59] A recent report highlights the relevance of antiglutamate receptor GluR ε2 autoantibodies in the cerebrospinal fluid and sera of a patient with RPC-associated limbic encephalitis.[60] The potential use of other biomarkers, such as urinary type II collagen neoepitope, has been highlighted in the literature.[23] A disease activity index for RPC was recently established and may have some value in the clinical assessment of patients with this rare disease.[61]

## TREATMENT

Nonsteroidal anti-inflammatory drugs and low-dose corticosteroids may successfully control minor inflammation of the nose, ear, or chest wall. Dapsone may also be used for noncritical cartilaginous inflammation,[1,62] and colchicine is of reported use in auricular chondritis.[63] However, the presence of potentially life-threatening disease or severe chondritis requires high-dose prednisone, typically at a dose of 1 mg/kg, reducing slowly as the inflammation recedes.[1,62] Although the RPC is usually steroid responsive, it can be difficult to withdraw these drugs completely without risking a flare in disease activity. Many patients require maintenance doses of prednisone and consideration of alternative immunosuppression. Disease-modifying treatment is indicated in patients who require a steroid-sparing agent, and/or in whom life-threatening manifestations have developed.

Because of the rarity of this disease, there are no controlled trials of therapeutic interventions in RPC. However, methotrexate, cyclophosphamide, mycophenolate mofetil, azathioprine, chlorambucil, and cyclosporine have had successful results in some patients.[34,63-70] Varied outcomes have been reported with leflunomide.[71,72] Plasmapheresis has been used in resistant cases.[34,73] Furthermore, intravenous immunoglobulin has been used successfully in recalcitrant RPC.[74] There are several case reports and small case series detailing the use of biologic agents in this disease. However, there have been variable data in relation to the antitumor necrosis factor agents. In those patients who responded to treatment, a sustained reduction in the acute phase response was noted during the period of study.[75-80] There are more negative than positive case reports in relation to the use of anti–B cell drugs in RPC.[75,81,82] IL-1 receptor antagonist has demonstrated benefit in a small number of reported cases.[83,84] Tocilizumab, an anti–IL-6 agent, has had beneficial effects in this disease, including cases of refractory inflammation and vascular involvement.[85-90] However, another report found a poor therapeutic response for this drug in RPC and suggested that it should be confined to use in patients with elevated serum IL-6, which might be predictive of efficacy.[91] Abatacept, a fusion protein of cytotoxic T lymphocyte–associated protein-4 (CTLA4) and IgG1, has shown efficacy, particularly for joint and cartilage inflammation in RPC, but may have little benefit for internal organ involvement.[92,93] A successful outcome for autologous stem cell transplantation in treatment-resistant RPC has also been reported.[94] It is not clear, however, if any of these treatments overtly influence the natural history of this disease.

A holistic approach to the management of RPC is essential. Awareness of disease complications and recognition of early pathology may be lifesaving. Special consideration should be given to the management of upper airway involvement, and the anesthesia team should be made aware of disease in this region before any surgical intervention. Symptomatic airway obstruction might require tracheostomy, tracheal stenting, or night-time positive pressure ventilation to prevent airway collapse while the patient is asleep. There is limited experience with laryngotracheal reconstruction in patients with this disease, and such interventions should only take place during disease quiescence.[95] Heart surgery to treat aortic root dilatation, aneurysm formation, or valvular disease has a good outcome in most cases, although post-operative dehiscence is a complication in 12%.[40,96,97] Most cases require post-operative immunosuppression. For patients with sensorineural deafness, cochlear implantation is usually beneficial with significant restoration of hearing.[98] The successful use of bone grafting to correct saddle nose deformity has been reported.[99,100] Neither hormonal activity nor pregnancy is thought to influence disease activity in RPC.[101] However, several case reports have described the treatment of disease flares during pregnancy, typically with corticosteroids, with successful maternal and fetal outcomes.[102-103]

## OUTCOME

RPC is an episodic, progressive disease that results in tissue destruction of target organs. Some patients have a mild course, complicated only by recurrent chondritis, whereas others develop potentially life-threatening problems. The most common cause of death is pulmonary infection, arising as a result of the disease or its immunosuppressive treatment.[34] In young patients, adverse prognostic factors at presentation include anemia, hematuria, upper airway disease, arthritis, and saddle nose deformity, whereas in older patients (older than 51 years), only anemia at presentation predicts increased mortality.[6] The presence of vasculitis worsens prognosis, with a 5-year survival rate of 45%.[36] In 1986, Michet and colleagues reported the 10-year survival rate to be 55%, whereas in 1998, perhaps because of improvements in disease monitoring and treatment, Trentham and colleagues described a 94% survival rate.[6,34]

## CONCLUSION

RPC is a systemic autoimmune disorder, characterized by episodic inflammation of cartilaginous structures (e.g., the upper aspect of the ears, proximal airways, eyes, kidneys, heart valves, and blood vessels). It may occur in isolation or in association with other inflammatory diseases. Involvement of the trachea or cardiovascular system may have life-threatening consequences. Immunosuppressive treatment, including the use of biologic agents, has been shown to abrogate disease features. A holistic approach is recommended to improve the morbidity and mortality of this rare condition.

CHAPTER 105

# Heritable Diseases of Connective Tissue

Deborah Krakow

**KEY POINTS**

- Heritable disorders of connective tissues are a genetically diverse group of disorders and are associated with extreme variation in height, from very short individuals (dwarves) to those with tall stature.
- The osteochondrodysplasias or skeletal dysplasias are a group of more than 450 distinct disorders frequently associated with profound short stature and orthopedic complications.
- These disorders are diagnosed based on radiographic, clinical, and molecular criteria.
- There has been significant progress in elucidating the underlying molecular mechanisms in most of these disorders, providing for improved clinical diagnosis and reproductive choices for affected individuals and their families.
- Treatment options have been used in osteogenesis imperfecta, metabolic storage disorders, and Marfan syndrome, which may improve the quality of life and life span in affected individuals.

Heritable disorders of connective tissues are a heterogenous group of disorders characterized by abnormalities in skeletal tissues, which include cartilage, bone, tendon ligament, and muscle. Disorders of connective tissues have been classified based on clinical findings and molecular criteria. They are subclassified into those that primarily affect cartilage and bone, which are the skeletal dysplasias, and those that have a more profound effect on connective tissue, which include the Ehlers-Danlos syndrome, Marfan syndrome, and other disorders caused by abnormal extra-cellular matrix molecules, such as cutis laxa syndrome resulting from mutations in the gene that encodes fibulin 5.[1] The skeletal dysplasias are associated with abnormalities in the size and shape of the appendicular and axial skeleton and frequently result in disproportionate short stature. Until the early 1960s, most individuals with short stature were considered to have pituitary dwarfism, achondroplasia (short-limbed dwarfism), or Morquio disease (short-trunked dwarfism). Presently, there are more than 450 well-characterized disorders that are classified primarily on the basis of clinical, radiographic, and molecular criteria. Disorders of connective tissues are genetic in origin and result from mutations in genes that encode extra-cellular matrix proteins, transcription factors, tumor suppressors, signal transducers, enzymes, chaperones, intra-cellular binding proteins, RNA-processing molecules, ciliary proteins, and genes of unknown function.[2]

## SKELETAL DYSPLASIAS

The skeletal dysplasias, or osteochondrodysplasias, are defined as disorders associated with a generalized abnormality in the skeletal. Although each skeletal dysplasia is relatively rare, collectively the birth incidence of these disorders is almost 1 in 5000.[3] These disorders range in severity from precious arthropathy to perinatal lethality caused by pulmonary insufficiency. Individuals with these disorders can have significant complications, including orthopedic, neurologic, and psychological. Many of these individuals seek medical attention for orthopedic complaints from ongoing pain, arthritic complaints in large joints, and back pain primarily caused by ongoing abnormalities in bone, cartilage, tendons, and ligaments.

### Embryology

The human skeleton (from the Greek *skeletos*, dried up) is a complex organ consisting of 206 bones (126 appendicular, 74 axial, 6 ossicles). The skeleton, including tendon, ligaments, and muscles in addition to cartilage and bone, has multiple embryonic origins and serves many key functions throughout life, including linear growth, mechanical support for movement, a blood and mineral reservoir, and protection of vital organs.

The patterning and architecture of the skeleton occurs during fetal development. During that period, the number, size, and the shape of the future skeletal elements are determined, and this process is under complex genetic control.[4] Uncondensed mesenchyme undergoes cellular condensations (cartilage anlagen) at sites of future bones, and this occurs by two mechanisms.[5] In the process of endochondral ossification, mesenchyme first differentiates into a cartilage model (anlagen), and then the center of the anlagen degrades, mineralizes, and is removed by osteoclast-like cells. This process spreads up and down the bones and allows for vascular invasion and influx of osteoprogenitor cells. The periosteum in the midshaft region of the bone produces osteoblasts, which then synthesis the cortex. This is known as the *primary ossification center*. At the ends of the cartilage anlagen, a similar process leading to the removal of cartilage occurs (secondary center of ossification), leaving a portion of cartilage model "trapped" between the expanding primary and secondary ossification center. This area is referred to as a *cartilage growth plate* or *epiphyses*. There are four chondrocyte cell types in the growth plate: reserve, resting, proliferative, and hypertrophic. These growth plate chondrocytes

undergo a tightly regulated program of proliferation, hypertrophy, degradation, and then replacement by bone, leading to the primary spongiosa. This is the major mechanism underlying skeletogenesis and is the means by which bones increase in length and the articular surfaces increase in diameter. In contrast, the flat bones of the cranial vault and part of the clavicles and pubis form by intramembraneous ossification, in which fibrous tissue, derived from mesenchymal cells, differentiate directly into osteoblasts, which then directly lay down bone. These processes are under specific temporal and genetic control, and abnormalities in the genes that encode these pathways frequently lead to skeletal dysplasias.[5]

## Cartilage Structure

Collagen accounts for two-thirds of the adult weight of adult articular cartilage and provide significant strength and structure to the tissue. Collagens are a family of proteins that consist of single molecules (monomers) that associate into three polypeptide chains to form a triple helix structure. In the triple helix, every third amino acid is a glycine residue, and the general chain structure is denoted as Gly-X-Y, where the X and Y amino acids are commonly proline and hydroxyproline. The collagen helix can be composed of identical chains (homotrimeric), as in type II collagen, or can consist of different collagen chains (heterotrimeric), as seen in type I collagen.[6]

Collagens are widely distributed throughout the body, and 33 collagen gene products are expressed in a tissue-specific manner, leading to 19 triple-helical collagens. Collagens are further classified by the structures they form in the extra-cellular matrix. The most abundant collagens are the fibrillar types (I, II, III, V, and XI), and their extensive cross-linking provides mechanical strength that is necessary for high-stress tissue, such as cartilage, bone, and skin.[7] Another collagen species is the fibril-associated collagens with interrupted triple helices (FACIT) and include types IX, XII, XIV, and XVI collagens. These collagens interact with fibrillar collagens as well as other extra-cellular molecules, including aggrecan, cartilage oligomatrix protein (COMP), and other sulfated proteoglycans.[8] Types VIII and X collagen are nonfibrillar, short-chain collagens, and type X collagen is the most abundant extra-cellular matrix molecule expressed by hypertrophic chondrocytes during endochondral ossification.[8] The major collagens of articular cartilage are fibrillar collagen, including types II, IX, XI, and X. In developing cartilage, the core fibrillar network is a cross-linked copolymer of types II, IX, and XI collagen,[9] and form the backbone complex to which other structural proteins bind. Mutations in genes that encode these collagens result in varying skeletal dysplasias (Table 105-1) and

highlight the importance of these molecules in skeletal development.

## Classification and Nomenclature

As mentioned above, in the 1970s there was recognition of the genetic and clinical heterogeneity of these disorders and a new awareness of the complexity of these disorders. As a result, there have been multiple attempts to classify these disorders in a manner that clinicians and scientists could effectively use to diagnose and determine their pathogenicity (International Nomenclature of Constitutional Diseases of Bone, 1970, 1977, 1983, 1992, 2001, 2005, and 2010).[2] The initial categories were purely descriptive and clinically based. With the recent explosion in determining the genetic basis of these diseases, the classification has evolved into one that combines the older clinical one (including the eponyms and Greek terms) and also blends these disorders into families that share a molecular basis or pathway. Some of the chondrodysplasia families are listed in Table 105-1. The most widely used method for differentiating the skeletal disorders has been through the detection of skeletal radiographic abnormalities. Radiographic classifications are based on the different parts of the long bones that are abnormal (epiphyses, metaphyses, diaphyses) (Figure 105-1). These epiphyseal, metaphyseal, and diaphyseal disorders can be further differentiated depending on whether or not the spine is involved (spondyloepiphyseal, spondylometaphyseal dysplasias, or spondyloepimetaphyseal dysplasias). Moreover, each of these classes of these disorders can be further differentiated into distinct disorders based on other clinical and radiographic findings.

## Clinical Evaluation and Features

The skeletal dysplasias are generalized disorders of the skeleton and usually result in disproportionate short stature. Affected individuals usually present with the complaint of disproportionate short stature, and this finding needs to be documented on the appropriate growth curves for sex and ethnicity if possible. As a general comment, most individuals with disproportionate short stature have skeletal dysplasias, and those with proportionate short stature have endocrine, nutritional, prenatal-onset growth deficiency, or other nonskeletal dysplasia genetic disorders. However, there are exceptions to the rule, such as congenital hypothyroidism, which is associated with disproportionate short stature, and disorders such as mild osteogenesis imperfecta and hypophosphatasia can be associated with relatively normal body proportions.

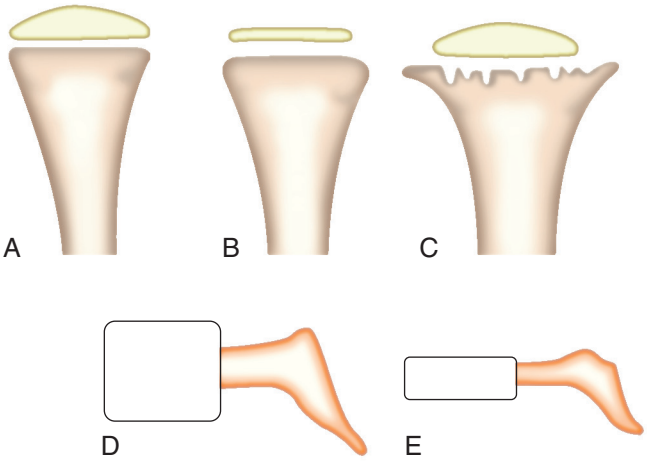

**Figure 105-1** Classification of chondrodysplasias based on radiographic involvement of the long bones **(A-C)** and vertebrae (**D** and **E**). **A** and **D** are normal. **B,** epiphyseal abnormality. **C,** metaphyseal abnormality. **E,** spondylo-abnormality.

A disproportionate body habitus may not be immediately visible on physical examination. Therefore the physician must take anthropodemetric measurements, such as upper/lower segment (U/L) ratio, sitting height, and arm span, when considering the possibility of a skeletal dysplasia, and measurements should be taken in centimeters. Sitting height is an accurate measure of head and trunk length, but it requires special equipment for precise measurements. Upper/lower ratios are easy to obtain and provide an accurate measurement of proportion. The lower segment is measured from the symphysis pubis to the floor at the inside of heel. The upper segment is measured by subtracting the lower segment measurement from the total height. For example, a Caucasian child between the ages of 8 to 10 years has a U/L segment ratio of approximately 1.0 and an U/L segment ratio of 0.95 as an adult. Individuals seen with disproportionate short stature will have altered ratios depending on whether they have short limbs, short trunk, or both. For example, an individual with short limbs and relatively normal trunk will have an increased U/L segment ratio, and an individual with relatively normal limbs but a short trunk will have a diminished U/L segment ratio (Figure 105-2). Another means of determining whether

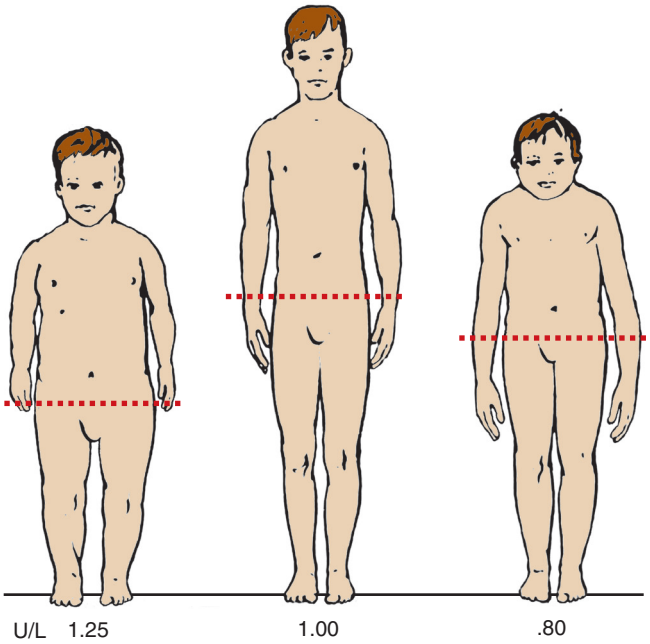

**Figure 105-2** Upper segment length/lower segment length in 8- to 10-year-old individuals with short-limb and short-trunk dwarfism. The child on the left has short limbs and an increased upper/lower ratio; the child on the right has a short trunk and reduced upper/lower ratio.

there is disproportion is based on arm span measurements, which are measured from tip to tip of the third finger. Arm span length is typically very close to total height (1:1) in an average-proportioned individual. A short-limbed individual will have an arm span considerably shorter than their height.

As in any disorder that has a genetic basis, it is critical for the physician to obtain an accurate family history, and this should include any history of previously affected children or parental consanguinity. The skeletal dysplasias are genetically heterogenous and can be inherited as autosomal dominant, autosomal recessive, X-linked recessive, and X-dominant disorders, and rarer genetic mechanisms of disease, including germline mosaicism, somatic mosaicism, uniparental disomy, and microdeletion syndromes, have been seen. For many patients and families, accurate diagnosis and recurrence risk can have significant impact on their reproductive decisions. Another consideration for patients with short stature is that there is increased nonassertive mating, which leads to reproductive outcomes that have been previously unknown.[10] For example, homozygous achondroplasia is lethal, and many newborns who inherit two dominant mutations (compound heterozygotes) do quite poorly because of increased lethality and severe effects on the skeleton.[11] The physician should also obtain accurate history relative to the onset of short stature and whether it developed immediately in the postnatal period or was noticed at age 2 or 3 years. Of the 450 skeletal dysplasias, approximately 100 of them have onset in the prenatal period, but many do not manifest disproportionate short stature and joint discomfort until childhood.[2]

A detailed physical examination may reveal a diagnosis or help differentiate the most likely group of possible diagnoses. It is critical that once disproportion and short stature has been established and the limbs are involved, to determine which segment is involved: upper segment (rhizomelic; humeri and femora), middle segment (mesomelic; radii, ulnae, tibiae, and fibulae), and distal segment (acromelic; hands and feet). Numerous head and facial dysmorphisms are seen in the skeletal disorders. Affected individuals frequently have disproportionately large heads or relative macrocephaly. Frontal bossing of the metopic bossing and flattened nasal bridge is very characteristic of achondroplasia, one of the most common skeletal dysplasias.[12] Cleft palate and micrognathia are commonly found in the type II collagen abnormalities, abnormally flattened of the midface with a turned-up nose is frequently found in the chondrodysplasia punctata disorders,[13] and abnormal swollen pinnae are seen in diastrophic dysplasia.[14] Individuals with skeletal dysplasias should be screened for ophthalmologic and hearing abnormalities because some of these disorders are associated with eye abnormalities and hearing loss.

Further evaluation of the hands and feet can lead to further differentiation of these disorders. Postaxial polydactyly is characteristically found in chondroectodermal dysplasia and the short-rib polydactyly syndrome disorders (see Table 105-1). Short, hypermobile, radially displaced thumbs and medially deviated halluxes are seen in diastrophic dysplasia. Nails can be abnormally hypoplastic in chondroectodermal dysplasia and short and broad in cartilage hair hypoplasia. Club feet or equinovarus may be seen in many disorders, including Kniest dysplasia, spondyloepiphyseal dysplasia congenita, Larsen syndrome, more severe forms of osteogenesis imperfecta, and diastrophic dysplasia. Bone fractures occur most commonly in two types of disorders: those that result from undermineralized bone (osteogenesis imperfecta, hypophosphatasia, achondrogenesis IA), or those that result from overmineralized bone (osteopetrosis syndromes and dysosteosclerosis).

Other organ systems, beyond the skeleton, can be involved though not commonly. Congenital cardiac defects are seen in chondroectodermal dysplasia (atrial septal defect), the short-rib polydactyly syndrome disorders (complex outlet defects, including isolated ventricular septal defects) and in Larsen syndrome (ventricular septal defect). Gastrointestinal anomalies are rare among the skeletal disorders, but congenital megacolon can be seen in cartilage hair hypoplasia, malabsorption syndrome in Shwachman-Diamond syndrome, and omphaloceles in otopalatodigital syndrome and atelosteogenesis I.

## Diagnostic Tests and Diagnosis

After obtaining a thorough family history and physical examination, the next step is to obtain a full set of skeletal radiographs or genetic skeletal survey. A full series of skeletal views, including anterior, lateral, and Towne views of the skull, anterior and lateral views of the entire spine, and anteroposterior pelvis and extremities, with separate views of the hands and feet, is optimal, especially after the newborn period. Most of the important clues to diagnosis are in skeletal radiographs that are obtained before puberty. Once the epiphyses have fused to the metaphyses, determining the precise diagnosis can be exceedingly challenging. If an adult is evaluated, all attempts should be made to obtain any available childhood radiographs. There are many subtle

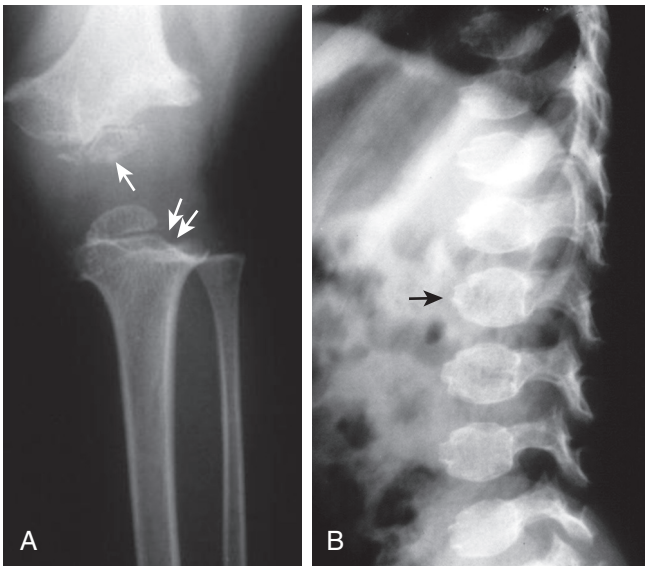

**Figure 105-3** Radiographs showing abnormalities. **A,** Distal femur and proximal tibia and fibula showing small irregular epiphyses *(single arrow)* and irregular metaphyses *(double arrows)*. **B,** Lateral view of the spine showing abnormally rounded vertebral bodies with anterior central beaking *(arrow)*.

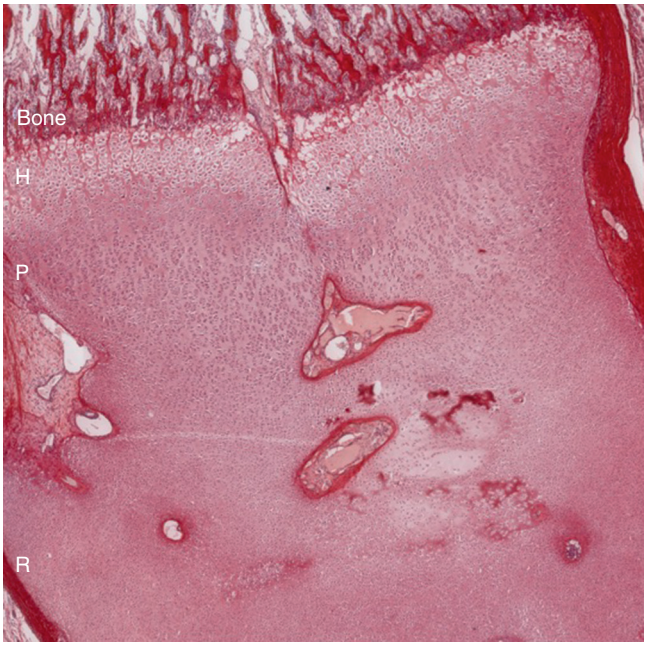

**Figure 105-4** Histologic analysis of a control 17-week human fetal growth plate stained with picrosirius red, showing the morphology of the growth plate. The defined zones of the growth plate are labeled, *H*, hypertrophic, *P*, proliferative, and *R*, resting.

clues in these skeletal radiographs that can lead to a precise diagnosis. For example, punctuate calcifications in the areas of the epiphyses in the chondrodysplasia punctata disorders, which are not seen in adulthood; multiple ossification centers of the calcaneus in more than 20 disorders[15]; and the pattern of hand shortening can aid in differentiating many disorders.

After obtaining radiographs, the physician should pay close attention to the specific parts of the skeleton (spine, limbs, pelvis, skull) involved and to the location of the lesions (epiphyses, metaphyses, and spondylcomponents) (Figure 105-3). As mentioned in preceding text, these radiographic abnormalities can change with age. If possible to obtain, radiographs of patients across a few ages will aid in diagnosis. Fractures can be seen in osteogenesis imperfecta (all types; see Table 105-1) and severe hypophosphatasia. In older individuals, fractures may be seen in disorders associated with increased mineralization, such as the osteopetrosis syndromes.

Morphologic studies of chondroosseus tissue have revealed specific abnormalities in many of the skeletal dysplasias.[16] In these disorders, histologic evaluation of chondroosseous morphology can aid in making an accurate diagnosis, and absence of histopathologic alterations can rule out diagnoses (Figure 105-4). These studies need to be performed on cartilage growth plate, and although commonly performed on perinatal lethal skeletal disorders at time of autopsy, obtaining growth plate histology on individuals with nonlethal disorders is difficult. If affected individuals (children) are undergoing surgery, an iliac crest biopsy can be evaluated, although admittedly this is performed with markedly less frequency than in the past, particularly while our molecular understanding has markedly increased. However, histomorphology studies done on these disorders have led to important insights on the pathogenesis of these disorders. On morphologic grounds, the chondrodysplasias can be broadly classified into those disorders that (1) have a qualitative abnormality in endochondral ossification, (2) have abnormalities in cellular morphology, (3) have abnormalities in matrix morphology, and (4) in which the abnormality is primarily localized to the area of chondroosseous transformation. For example, in thanatophoric dysplasia, there is a defect in endochondral ossification with a very short, if almost hypertrophic, zone, a shortened proliferative zone, and overgrowth of the periosteum. In pseudoachondroplasia, there is a distinct lamellar pattern (alternating electron-dense and electron-lucent lamellae) in the rough endoplasmic reticulum of chondrocytes and a grossly abnormal matrix in diastrophic dysplasia, which leads to a characteristic ring around the chondrocytes. All of these findings are characteristic and diagnostic for these disorders and illustrates how morphology studies can play in integral part in the investigation of these disorders. Further, disorders across a phenotypic spectrum have been placed in bone families based on similar cartilage growth plate morphologic abnormalities.

There has been significant progress in gene identification in these disorders, which has impact for affected individuals. As illustrated in Table 105-1, for those disorders in which the gene is identified, molecular diagnostic testing is potentially available. Molecular diagnosis can be used to confirm a clinical and radiographic diagnosis, predict carrier status in those families at risk for a recessive disorder, and, for some individuals, allow prenatal diagnosis of at-risk fetuses. With commercial availability of whole-exome sequence analysis, many high and low bone mass parallel sequencing panels are available, as well as whole-exome sequence analysis for rare disorders not available on panels. If there is no question regarding definitive diagnosis, then disease genes can be directly interrogated. GeneTests (www.genetests.org) is a

publically funded medical genetics website developed for physicians that provides information on specific diseases and available genetic testing.

## Treatment

The optimal management of this diverse set of disorders requires an understanding of their medical, skeletal, and psychosocial consequences. This is often best accomplished by centers that have a multidisciplinary approach, which include adult and pediatric physicians, as well as a group of physicians, geneticists, orthopedists, rheumatologists, otolaryngologists, neurologists, neurosurgeons, and ophthalmologists who are committed to the care of these patients.

Most medical complications in these disorders result from orthopedic complications, and they vary depending on the specific disorder. For example, in disorders associated with significant odontoid hypoplasia, such as Morquio disease, type II collagenopathies, metatropic dysplasia, and Larsen syndrome, flexion-extension films should be monitored at regular intervals to assess C1-C2 subluxation. If there is evidence for subluxation, surgery for C1-C2 fixation is indicated. Many geneticists support flexion and extension radiographic evaluation, including MRI of the neck in all cases of skeletal dysplasias, because so many of these disorders have cervical vertebral abnormalities.[17] Genu varum, lateral curvature of the lower extremity, is common in many skeletal disorders because of overgrowth of the fibula. This causes knee or ankle pain in many individuals, especially children, and consideration should be made for correction by osteotomies. Children and adults with skeletal dysplasias should have regular eye and hearing examinations because they are at increased risk for myopia, retinal degeneration, glaucoma, and hearing loss, depending on the disorder.

Frequently, patients with these disorders have significant joint pain and, in some cases, joint limitations. Because most of these disorders result from mutations in genes critical to cartilage function, the cartilage at the joint surfaces may not provide adequate support and cushioning function. Many of these patients seek attention for joint pain. Evaluation should include radiographic views and MRI, when appropriate, to determine the etiology of the pain. In some disorders (e.g., the type II collagenopathies, pseudoachondroplasia, multiple epiphyseal dysplasia, and cartilage hair hypoplasia), by adulthood so little cartilage remains at the knee or hips that joint replacement is indicated for pain relief. Last, weight control in adults with short stature is an ongoing issue and contributes to inactivity, loss of function, adult-onset diabetes, hypertension, and coronary disease.[18]

Achondroplasia is the most common of the nonlethal skeletal dysplasias (approximately 1/20,000) and serves as an example on how to approach these disorders, particularly because the incidence and type of medical complications change during the life span of the individual. The majority of these individuals are of normal intelligence, have a normal life span, and lead independent and productive lives. The mean final height in achondroplasia is 130 cm for men and 125 cm for women, and specific growth charts have been developed to document and track linear growth, head circumference, and weight in these individuals.[19,20]

In early infancy, there is potentially serious compression of the cervicomedullary spinal cord secondary to a narrow foramen magnum, cervical canal, or both. Clinically, these infants show central apnea, sleep apnea, profound hypotonia, motor delay, or excessive sweating. MRI with flow studies is necessary to document the obstruction and, if present, requires decompression surgery. Other complications include upper airway obstruction, thoracolumbar kyphosis, and hydrocephalous in a small number of individuals.[21] From early childhood and while the child begins to walk, several orthopedic manifestations occur, including progressive bowing of the legs because of fibular overgrowth, lumbar lordosis, and hip flexion contractures. Recurrent ear infections lead to chronic serous otitis media and deafness. Tympanic membrane tube placement is indicated in many of these patients. Craniofacial abnormalities lead to dental malocclusion, and appropriate treatment is necessary. As adults, the main potential medical complication is impingement of the spinal root canals, and this can be manifested by lower limb paresthesias, claudication, clonus, bladder, or bowel dysfunction. It is critical that these complaints are addressed because without appropriate decompression surgery, paralysis of the spinal cord can result.[21]

Growth hormone has not been effective in increasing height in this disorder.[22] Surgical limb lengthening has been used successfully to increase limb length by as much as 12 inches,[23] but patients need to recognize that this technique needs to be done during the teen years, is performed during a 2-year period, and is associated with complications. Because of the discovery of the disease gene in 1994,[24] the molecular consequences of the activating mutation in fibroblast growth factor receptor 3 gene *(FGFR3)* have been elucidated. Although the mutation has numerous effects on receptor kinase signaling pathways, increased activation of ERK (mitogen-activated protein kinase) is responsible for much of the proliferation defect seen in achondroplasia cartilage growth plates.[25] Inhibitors of the pathway have been identified and potential treatments are being proposed.[26]

Throughout their lives, individuals with achondroplasia, other skeletal dysplasias, and their families experience various psychosocial challenges.[27] This can be addressed by specialized medical and social support systems. Interactions with advocacy groups such as *Little People of America* (*LPA*; http://www.lpaonline.org) can provide both emotional support and medical information.

## Biochemical and Molecular Abnormalities

Based on clinical, radiographic, and histomorphologic similarities, skeletal dysplasias have been placed into bone dysplasia families.[28] These families share a common pathophysiologic or pathway mechanisms. In recent years, there has been an explosion in our understanding of the basic biology of these disorders. This has resulted from advances in the human genome project that improved various methodology, including candidate gene approach, linkage analysis, positional cloning, human/mouse synteny, whole-exome and whole-genome analysis, allowing identification of the responsible disease genes (see Table 105-1). With gene discovery in more than 350 of these osteochondrodysplasias, these genes can be placed into several categories

designed to understand their pathogenesis: (1) defects in extra-cellular proteins, (2) defects in metabolic pathways (enzymes, ion channels, and transporters), (3) defects in folding and degradation of macromolecules, (4) defects in hormones and signal transduction, (5) defects in nuclear proteins, (6) defects in oncogenes and tumor suppressor genes, (7) defects in RNA and DNA processing molecules, (8) defects in intra-cellular structural proteins, (9) defects in chaperones, (10) defects in ciliary components, and (11) genes of unknown function. There are still skeletal dysplasias for which the disease-producing genes are unknown. Below are just some examples of the molecular mechanisms involved in the skeletal dysplasias.

## DEFECTS IN EXTRA-CELLULAR STRUCTURAL PROTEINS

### Type II Collagen and Type XI Collagen

Because type II collagen was found primarily in cartilage, the nucleus pulposus, and the vitreous of the eye, it was hypothesized that skeletal disorders with significant spine and eye abnormalities would result from defects in type II collagen. Indeed, type II collagen defects have been identified in a spectrum of disorders ranging from lethal to mild arthropathy, which include achondrogenesis II, hypochondrochogenesis, spondyloepiphyseal dysplasia congenital, spondyloperipheral, spondyloepimetaphyseal dysplasia, Strudwick type, Kniest dysplasia, Stickler syndrome, and "precocious" familial arthropathy. These disorders are referred to as *type II collagenopathies*, and they all result from heterozygosity for mutations in the gene *COL2A1*, which encodes type II collagen.[29,30] Biochemical analysis of cartilage derived from these individuals shows electrophoretically detectable abnormal type II collagen. Further, type I collagen is not normally present in cartilage; however, in the presence of abnormal type II collagen, there is increased type I collagen in the growth plate.

Mutations that result in a substitution for a triple-helical glycine residue appear to be the most common type of mutation.[31-33] There are some correlations between the location of the mutation and the disease phenotype. In spondyloepiphyseal dysplasia congenita (SEDC), the glycine substitutions are scattered throughout the molecule; however, in Kniest dysplasia, the mutations are in the more amino-terminal end of the molecule.[34-36] Stickler syndrome is genetically heterogenous and results from mutations in *COL2A1* and *COL11A1*, and non-ocular forms in *COL11A2*.[37,38] In Stickler syndrome, the *COL2A1* and *COL11A1* mutations tend to be nonsense mutations resulting in premature translation stop codons; however, patients with *COL11A1* mutations tend to have a more severe eye phenotype and hearing loss than patients with *COL2A1* mutations.

Individuals heterozygous for various *COL11A2* mutations have a non-ocular form of Stickler syndrome, which is consistent with the absent expression of *COL11A2* in the vitreous humor. Otospondylomegaepiphyseal dysplasia (OSMED) is a rare autosomal recessive disorder caused by loss of function mutations in *COL11A2*.[39] This disorder has radiographic similarities to Kniest dysplasia but is associated with profound sensorineural hearing loss and lack of ocular involvement. To add to the spectrum of type XI mutations, both dominantly and recessively inherited mutations in *COL11A1* and *COL11A2*, respectively, can produce the very severe skeletal dysplasia, fibrochondrogenesis.[40,41]

### Cartilage Oligomeric Matrix Protein

Heterozygosity for mutations in COMP lead to both pseudoachondroplasia and multiple epiphyseal dysplasia.[42] COMP is a member of the thrombospondin family of protein and consists of an epidermal growth factor domain and a calcium-binding calmodulin domain.[43] In both pseudoachondroplasia and MED, disease-producing mutations occur in the calmodulin domain, with a minority in the globular carboxyterminal domain. Both these disorders are associated with early-onset osteoarthritis, particularly of the hips and the knee, leading to joint replacements in many individuals in early adulthood.[44]

### Conclusion

Although these osteochondrodysplasias are relatively rare disorders, affected individuals have significant skeletal complications throughout their lives, first because of patterning defects, then effects on linear growth, and, finally, loss of normal structural cartilage as a cushion later in life. The explosion in delineating molecular defects has shown the complexity of cartilage as a tissue and the large number of cellular processes necessary for a normal skeleton.

## OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta (OI) is a heritable disorder of bone and was one of the first genetic disorders hypothesized to be a defect in collagen.[45] Although an osteochondrodysplasia, it will be discussed separately from the chondrodysplasias delineated above. OI is actually a generalized disorder of connective tissue that predominantly affects the skeletal system and affects a significant numbers of individuals (estimates at approximately 1/20,000 individuals)

Initially, there were four types of recognized OI in the clinical classification of Sillence.[46] However, there are now numerous types of recognized OI on the basis of expanding genetic heterogeneity, yet most of the forms of OI can still be classified into mild, moderate, severe, and lethal. Because there is enormous clinical variability in these types, the subtypes will be discussed separately (Table 105-2). However, these disorders all share the same phenotypic finding of hypomineralization of the skeleton, although interesting bone quality is associated with overbrittleness.[47]

### Mild Osteogenesis Imperfecta (Type I OI)

Affected individuals with type I OI disease have relatively mild severity in terms of their clinical course, the extent of skeletal deformity, and the radiologic appearance of the skeleton (see Table 105-2). They also account for the vast majority of individuals with OI. Individuals usually have mild short stature for their age or their unaffected family members, but are not as severe as seen in the other forms. Many of these individuals experience numerous fractures, especially in childhood, and it is common for

**TABLE 105-2** Classification and Molecular Basis of Osteogenesis Imperfecta (OI)

| Sillence Classification | OI Phenotypic Grouping | Mode of Inheritance | Biochemical Findings | Gene(s) | Mechanisms |
|---|---|---|---|---|---|
| I | Mild | AD | 50% reduction in type I collagen synthesis | *COL1A1*<br>*COL1A2* | Structural defects<br>Haploinsufficiency |

*Sillence classification: original osteogenesis imperfecta classification.
AD, Autosomal dominant; AR, autosomal recessive.

them to have has as many as twenty fractures by the age of five.

The disorder is autosomal dominant, and in many cases, the individual is the first affected in their family. Their sclerae are blue that becomes gray to pale blue in adulthood. Arcus senilis not related to lipid abnormalities may occur in some patients. Other reported ocular defects include scleromalacia, keratoconus, and retinal hemorrhage.[48] Their teeth frequently show dentinogenesis imperfecta (DI) because of the effects of mutation on the tooth dentin.[49] The deciduous and permanent teeth have an opalescent and translucent appearance, which tends to darken with age. The enamel is normal, but the dentin is dysplastic; chipping of enamel occurs, and the teeth are subjected to erosion and breakage. Affected individuals' teeth appear discolored or gray; this finding is variable in the disorder but does cosegregate in families with OI. DI can be seen in all forms of OI.

During the second and third decades of life, a characteristic high-frequency sensorineural or mixed hearing loss can be detected.[50] The incidence of mitral valve prolapse is not increased in these patients compared with the population at large, but individual kindreds with increased diameter of the aortic root or patients with aortic regurgitation have been reported.[51] Many patients complain of easy bruising, and this may result from the effects of mutation on both skin and the vessels below.

Mildly affected patients may not have fractures at birth, although there is occasionally a fracture of a clavicle or extremity during delivery. Radiographically, affected newborns have wormian bones seen on lateral views of the skull, with significant osteopenia seen through the skeleton, especially the spine. The frequency of fracture thereafter depends on the child's activity, the need for immobilization after lower extremity fractures, and the attitude of the family toward independent activity. In general, these patients may experience 5 to 15 major fractures before puberty, as well as several minor traumatic fractures of the digits or the small bones of the feet. Characteristically, the fracture rate falls dramatically after puberty, only to increase during later life. Mild scoliosis approximating 20 degrees is common. Osteopenia is observed in vertebral bodies and the peripheral skeleton and progresses with age. It is remarkable that in type I OI the long bones usually heal with no significant deformity. When compared with more severe phenotypes, children with type I OI only infrequently require the insertion of intramedullary rods and almost never experience nonunion at a fracture site.

Although osteopenia with rarefaction of the medullary space and cortical thinning are observed in radiographs, many type I cases are so mild as to be missed on routine radiographic examination. Measurement of bone mineral density (BMD) by dual-energy x-ray absorptiometry (DEXA) at any age discloses a significant decrease in bone mass. T scores (i.e., standard deviation from the young-adult mean BMD) are frequently in the range of −2.5 to −4.0 at the lumbar spine or proximal femur, consistent with the diagnosis of osteoporosis as defined by the World Health Organization (WHO). Low BMD in children with recurrent fractures may assist in identifying those with OI.

### Molecular Pathology

Type I OI results from mutations affecting the COL1A1(I) and COL1A2(I) polypeptide chains of type I collagen. Cultured fibroblasts from individuals with mild OI synthesize low amounts (approximately one-half) of the expected amounts of type I collagen. Most of the reported mutations in type I OI are nonsense and frameshift mutations and thus are predicted to lead to premature termination codons, although there are some exceptions.[52,53]

## Lethal Osteogenesis Imperfecta (Type II OI)

Approximately 10% of patients with OI have the severe neonatal form of the disease, lethal osteogenesis imperfecta. Most cases result from sporadic mutations, however, recessively inherited forms of the disease has recently been documented.[54-56] These infants are seen with severe bone fragility, multiple intrauterine fractures at various stages of healing, deformed extremities and, occasionally, hydrops fetalis. Radiographic features include wormian bones, multiple fractures, crumbled bones and characteristic beading of the ribs caused by healing callus formation.

### Molecular Pathology

Most cases occur de novo as new dominant mutations; however, autosomal recessive forms have been established, as has recurrence based on germline mosaicism.[57] The biochemical abnormality in lethal OI is the inability to synthesize and secrete normal type I collagen.[57] As a result, the amount of type I collagen in bone is low, much of the secreted collagen is abnormally overmodified, and the quantity of the minor collagens, types III and V, is relatively high. Bone collagen fibers are thinner than normal, and at the intra-cellular level type I collagen in retained within dilated endoplasmic reticulum.

Similar to most cases of OI, mutations in the genes encoding COL1A1 and COL1A2A lead to the dominant or de novo form of lethal OI.[58] Single glycine substitution with the Gly-X-Y triplet of either *COL1A1*and *COL1A2* lead to this form of OI, as do some small deletions, all producing severe effects on the triple helix. Recessive form accounts for a small number of these cases and the involved genes are listed in Table 105-2. Some of these recessive forms result from mutations in the genes encoding either *CRTAP* (cartilage-associated protein), *P3H1* (prolyl-3-hydroxylase 1), or *PPBI* (Cyclophilin B). These molecules form a complex that hydroxylate (add an –OH group) to a third-position residue at proline 986 (Pro986). This modification of a single residue is thought to stabilize the collagen helix, although the mechanism of disease production is probably much more complicated, and this complex may act as a chaperone complex.

## Severely Deforming Osteogenesis Imperfecta (Type III OI)

The deforming variant of osteogenesis imperfecta is the classic form of OI. Similar to lethal OI (type II OI), most cases are inherited as autosomal dominant (or de novo), although recurrent cases based on autosomal recessive inheritance resulting from mutations in numerous recessively inherited genes have been recently demonstrated (see Table 105-2). This variant of OI is characterized by severe deformity of the limbs and marked kyphoscoliosis, thorax deformity, and significant short stature. The extent of growth retardation is remarkable, and in many adults the height may not surpass 3 ft (90 to 100 cm). Abnormal cranial molding occurs in utero and during infancy, producing frontal bossing and a characteristic triangular-shaped facies. Radiographically, wormian bones and delayed closure of the fontanelles may be observed well into the first decade.

Pulmonary function can be diminished because of distortion of the spine and thorax and can progress with time and lead to restrictive lung disease and sleep apnea. Unfortunately, because of diminished vital capacity, pulmonary insufficiency is a leading cause of death in subjects with type III OI. Respiratory compromise develops in many patients with scoliosis greater than 60 degrees, creating a need for pulmonary investigations. Many of these individuals need supplemental oxygen.

Platybasia resulting from soft bone at the base of the skull may cause the external ear canals to slant upward while the base of the skull sinks on the cervical vertebrae. This distortion may lead to communicating or obstructive hydrocephalus, cranial nerve palsies, and upper and lower motor neuron lesions. Headache, diplopia, nystagmus, cranial nerve neuralgia, decline in motor function, urinary dysfunction, and respiratory compromise are complications of basilar invagination.[59] As opposed to type I OI, most affected patients with type III OI have white sclera as adults. Approximately 25% of patients with type III OI have dentinogenesis imperfecta, necessitating constant dental care throughout childhood. Severe hearing impairment occurs in 10% of patients, although milder degrees of hearing loss are more common.

The skeleton in these patients has significant osteopenia, leading to multiple fractures in the upper and lower extremities and vertebral bodies, particularly before puberty. Unlike type I OI, in which fractures tend to heal without deformity, fractures in type III OI frequently lead to skeletal deformity. Radiographs of the skeleton reveal marked osteopenia, thinning of cortical bone, narrowing of the diaphysis, widening of the metaphysis, which merges into a dysplastic epiphyseal zone filled with whorls of partially calcified cartilage (i.e., popcorn deformity).[60] Osteoporosis leads to collapse of vertebral end plates contributing to worsening kyphoscoliosis. Pectus excavatum or pectus carinatum adds to thoracic deformity.[61] In addition, lack of weight bearing increases the severity of osteoporosis and increases the risk of fracture. Many of the individuals become wheelchair bound at an early age or walk with mechanical assistance.

### Molecular Pathology

The molecular basis of type III OI is very similar to type II OI. Most of the cases result from heterozygosity for mutations in *COL1A1* and *COL1A2*. These mutations are glycine substitutions scattered through the triple helix, as well as in-frame deletions. As in type II OI, familial

recurrences result from recessively inherited mutations in numerous genes listed in Table 105-2.

## Osteogenesis Imperfecta of Moderate Severity (Type IV OI)

Clinically, the phenotype of patients with moderately severe OI (type IV OI) falls between the milder type I and type III OI, and this diagnosis is somewhat subjective. In most cases, this type is usually inherited in an autosomal dominant fashion. Fractures are rarely at birth, and some patients may not have the initial fracture until later in the first decade. The extent of skeletal deformity involving the spine, thorax, and extremities is usually intermediate between that of types I and III OI, and these patients have short stature and frequently have scoliosis. The patients may have some mild facial dysmorphisms but not as severe as type III OI. Hearing loss occurs but less than in types I and III OI.

Most fractures occur during childhood and may reoccur during the post-menopausal period in women or in men older than age 50 years.[61] Long-bone deformity tends to develop after fractures, which may lead to a difficulty in ambulation. Radiographs of the long bones and vertebral bodies demonstrate marked osteopenia with vertebral collapse. Although there is marked cortical thinning, bowing, and coarsening of trabeculae, the overall architecture of the bone is normal.

### Molecular Pathology

The molecular mechanisms for type IV OI are similar to the other forms. The mutations are in *COL1A1* and *COL1A2* and include glycine substitution and in-frame deletions. At the present time, there is no evidence for an autosomal recessive form of type IV OI.

## Type V Osteogenesis Imperfecta

This phenotype was reported by in 2000 as a variant within the heterogeneous group classified under type IV OI.[62] In the initial report of seven patients with OI, the phenotype was distinguished by the following criteria: moderate fracture history, hyperplastic callus formation, limitation in forearm pronation and supination due to intramembraneous bone formation at the joint, normal sclera, and no DI. Bone biopsy showed a meshlike appearance of irregularly spaced lamellae, different from the woven bone seen in types II, III, and IV OI. This etiology of this rare form has been established and results from heterozygosity for mutations in *IFITM5*.[63]

## Histopathology of Bone in Osteogenesis Imperfecta

The range of histologic appearances of bone in the different OI phenotypes is as variable as the clinical phenotypes. Undermineralization and overmineralization of bone have been recognized within the same specimen.[47] Bone histomorphology appears relatively normal in type I OI, but osteopenia caused by thin lamellar plates and diminished cortical width is evident. Immature woven bone and lamellar disarray are characteristic of more severe OI phenotypes.[47]

## Treatment

During the years, there have been multiple attempts to treat OI with a variety of vitamins, hormones, and drugs, none of which has been successful. The list includes administration of mineral supplements, fluoride, androgenic steroids, ascorbic acid, and vitamin D. During the last 15 years, bisphosphonates administered parenterally to children has demonstrated favorable results. Intravenously administered bisphosphonate pamidronate increased bone mass, decreased skeletal pain, and decreased fracture incidence in children with severe OI.[64] Dosage regimens in different series for children and adults have varied from 1 mg/kg to 3 mg/kg, administered intravenously at 2- to 4-month intervals, and lower-dosage regimens also have been reported.[64] In general, reports indicate a significant increase in bone mass in children and a decrease in fracture rate. The effect is most marked in the spine, where vertebral remodeling may improve vertebral height. Metabolic studies by have demonstrated a decrease in serum ionized calcium and increase in serum parathyroid hormone (PTH). The major side effects of intravenous (IV) bisphosphonate treatment involve the acute phase response (24 hours after infusion) and the occurrence of otitis and vestibular imbalance in a small number of patients. The currently recommended treatment regimen includes the use of a bisphosphonate with adequate calcium and vitamin D supplementation to avoid the occurrence of hypercalciuria and to maintain serum vitamin D levels within normal limits. Recently, the use of anabolic treatment to build bone has been tested by using teriparatide in adult patients in OI, and the study showed that patients with mild OI, but not severe OI, benefited from treatment.[65]

The use of surgery to correct deformities and to facilitate weight bearing has been the subject of several reviews.[66] Multiple osteotomies and realignment of a deformed bone over intramedullary rods is an option for many children with severe bowing.[67] Indications include frequent fractures at the apex of the bow, impaired standing, or limb-length inequality resulting from bowing.[68] Expanding (telescoping) rods are best for growing children, for they require fewer revisions. Spinal deformities are common and usually progressive. Surgical stabilization is most advisable in the teen years or early adulthood when patients are best able to tolerate these complex reconstructions.[69] Early basilar invagination may be halted with prophylactic posterior fusion of the occipital-cervical junction with plate fixation.[70] Patients with severe brain stem compression may require anterior transoral decompression, as well as posterior instrumented fusion. Patients with various types of OI appear to be at increased risk of premature OA, and the reasons for this are not clear. Total joint arthroplasty is usually successful in these patients, thus referral is appropriate.[71]

Every child with OI benefits from appropriate rehabilitative therapy.[72] Bracing with lightweight plastics while the child begins to walk can minimize microfracture and bowing of the upper femurs. Muscle-strengthening exercises are essential as primary care and after immobilization for fracture. Perhaps the most beneficial programs have been

developed around swimming, preferably in heated pools, and as part of continuous rehabilitative medical care.

## EHLERS-DANLOS SYNDROME

The heterogenous group of disorders grouped together as Ehlers-Danlos syndrome (EDS) illustrates the genetic and clinical variability characteristic of the heritable disorders of connective tissue. The most cardinal feature of these disorders is the presence of joint hypermobility, associated with an increase in skin elasticity and skin fragility. There are more than 10 recognized types of EDS, and in 1997, a simplified classification was proposed, dividing EDS into six major clinical types. The classification includes the types of classic, hypermobility, vascular, kyphoscoliosis type, arthrochalasia, and dermosparasix, and several rarer EDS types, grouped into "other forms."[73] However, clinically EDS can be difficult to separate because of considerable overlap in phenotype findings.

### Ehlers-Danlos Syndrome (Classic Type)

#### Clinical Features

This autosomal dominant type of EDS accounts for approximately 80% of the reported cases[74] and is inherited as an autosomal dominant trait. Originally, EDS was classified as types I and II, and now they are classified as the classic form, although these subclassifications are still in use by some clinicians. Previously, they were distinguished from each other based on joint laxity and skin fragility, which are less severe than in type II EDS. Most prototypic forms of EDS are characterized by varying degrees of hyperextensibility of large and small joints and are classic findings in EDS. Thus it is critical that hyperextensibility be defined, and differentiating mild "normal" laxity from hyperextensibility can be challenging. Beighton has presented a clinically useful classification of joint laxity.[74]

1. Passive dorsiflexion of the fifth digit beyond 90 degrees = one point for each hand
2. Passive apposition of the thumbs to the flexor surface of the radius = one point for each hand
3. Hyperextension of the elbows beyond 10 degrees = one point for each side
4. Hyperextension of the knees beyond 10 degrees = one point for each knee
5. Flexion of the trunk forward so that the palms are placed flat on the ground = one point

A score of five or more points is defined as joint hypermobility.

Large-joint hyperextensibility is seen in varying degrees in the classic form and decreases with age. Recurrent joint dislocations, periodic joint effusion related to trauma, and the eventual appearance of OA pose significant management problems. Bilateral synovial thickening has been observed in EDS, along with the accumulation of small masses of crystalline material in synovial villi. It was observed that patients with EDS constituted 5% of cases in a pediatric arthritis clinic population.[75] There is debate about whether affected infants may be born prematurely to affected mothers because of early rupture of amniotic membranes.[76] Patients with EDS have characteristic facies, with a broad nasal root and epicanthal folds. They may have large, lax ears, and traction on the ears or elbows reveals skin hyperextensibility. Another sign of hypermobility is the ability to touch the tip of the tongue to the nose (Gorlin's sign).[77,78] In addition, absence of the lingual frenulum is characteristic for this disorder.[77]

In EDS the skin has a characteristic soft or "velvety" feel that can be appreciated by stroking of the forearms. Thin, atrophic corrugated and hyperpigmented scars are found on the forehead, under the chin, and on the lower extremities (known as *cigarette paper* or *papyraceous* scars), although this is not a uniform finding. Typically, skin lesions heal slowly after injury or surgery. Molluscoid pseudotumors (violaceous subcutaneous tumors ranging in size from 0.5 to 3 cm) may be palpated in tissue over pressure points on the forearms and lower extremities and may be seen on radiographs. Although many patients claim to bruise easily, ecchymoses distributed on the extremities are found only in patients with the more severe forms of the disorder. Severe bilateral varicose veins are a common problem.

Associated pulmonary complications of EDS include spontaneous pneumothorax, pneumomediastinum, and subpleural blebs.[79] Mitral valve prolapse and tricuspid valve insufficiency may complicate the classic EDS, and aortic root dilatation has been reported, although the rate of progression is unknown.[80,81] The spectrum of skeletal abnormalities include thoracolumbar kyphoscoliosis, a long, giraffe-like neck, downward sloping of the ribs of the upper part of the thorax, and a tendency toward reversal of the normal cervical, thoracic, and lumbar curves. Anterior wedging of thoracic vertebral bodies occasionally is seen.

### Ehlers-Danlos Syndrome (Hypermobility Type)

The hypermobile type of EDS is a dominantly inherited disorder that presents as marked joint and spine hypermobility, recurrent joint dislocations, and the typical soft skin that is neither hyperextensible nor velvety. Individuals with EDS III may have virtually normal skin. Because of the extent of joint laxity affecting both large and small joints, these patients experience multiple dislocations and may require surgical repair. The shoulders, patellae, and temporomandibular joints are frequently sites of dislocation. Musculoskeletal pain may mimic that of the fibromyalgia syndrome, and patients frequently seek medical attention for symptoms consistent with chronic pain.

One of the difficulties in this subtype is differentiating it from benign hypermobility syndrome. Benign hypermobility syndrome was used to describe patients with generalized joint laxity, associated musculoskeletal complaints, but normal skin.[82] They do not have the classic stigmata of either EDS or Marfan syndrome. Many of these patients are seen in their twenties and thirties with rheumatologic symptoms that can pose problems in diagnosis and treatment. The precise approach and treatment for these patients is not clear.

### Structural and Molecular Pathology of the Classic and Hypermobile Type of Ehlers-Danlos Syndrome

Abnormally large, small, or frayed dermal collagen fibrils and disordered elastic fibers have been observed in the classic and hypermobile forms of EDS by electromicroscopy.[83]

Type V collagen is a heterotrimeric collagen composed of the products of three genes: *COL5A(V)*, *COL5A(V)*, and *COL5A(V)*. Type V collagen may stabilize type I collagen by co-assembling with that protein. It has been established that approximately 50% of patients with either the classic or hypermobility types of EDS have mutations in *COL5A1(V)* or *COL5A2(V)*.[84] Furthermore, in some cases of EDS classic type a heterozygosity for mutations in *COL1A1* has been seen.[85]

## Ehlers-Danlos Syndrome (Vascular Type)

This autosomal dominant disorder is one of the most severe forms of EDS and was formerly referred to as *EDS type IV*. It is associated with arterial rupture, commonly involving iliac, splenic, renal arteries, or the aorta, and resulting in either massive hematomas or death.[86] Arterial rupture may lead to stroke or intracompartmental bleeding in a limb. Patients with this disorder are also susceptible to rupture of internal viscera and may experience repeated rupture of diverticula on the antimesenteric border of the large bowel. Problems with pregnancy vary from pre-term delivery to uterine or vascular rupture, although delivery is uneventful in many instances.[87,88] Typical causes of death in families with EDS have included gastrointestinal rupture, peripartum uterine rupture, rupture of the hepatic artery, and vascular ruptures.

In contrast to the other forms of EDS, EDS IV is not associated with hyperextensibility of large joints, although small joints may be minimally hypermobile. These patients have thin, soft, transparent skin, through which a prominent venous pattern is seen, especially on their chest walls. Their skin is not "doughy" as in the classic form. Excessive bruisability may occur. Vascular EDS includes, as a subgroup, patients who have been described as *acrogyric*. These individuals have characteristic thin faces, prominent eyes, and extremities that lack subcutaneous fat, giving the appearance of premature aging. Peripheral joint contractures and acro-osteolysis have been described.[89] Spontaneous hemopneumothorax associated with hemoptysis and mitral valve prolapse occurs frequently.[90] Surgical repair of ruptured vessels or internal viscera is extremely difficult because of friable tissues. Anesthetic and surgical difficulties related to intubation, spontaneous arterial bleeding during surgery, and the ligation of vessels that tear under pressure complicate surgical maneuvers. Similarly, arteriography may be dangerous in these patients. These patients can be quite difficult to manage. Imaging studies may reveal normal-appearing aorta or other large vessels that rupture shortly after a "normal study."

### Molecular Pathology

Although EDS IV was clinically recognized as a disorder distinct from the other forms of EDS, the finding that tissues from these individuals were deficient in type III collagen clearly distinguished this as a separate form of EDS. Type III collagen is a homotrimer (1[III]3) found in skin, blood vessels, and the walls of hollow viscera. Heterozygosity for mutations in the gene encoding *COL3A1* leads to EDS vascular type and affects both the synthesis and secretion of type III collagen.[90-92] Various types of mutations have been identified, including missense, nonsense, and deletions, and there is no correlation between the clinical phenotype and type of type III collagen mutation. In this disorder biochemical abnormalities include decreased production of type III collagen or production of an abnormal homotrimer that is retained in the endoplasmic reticulum and, if secreted, contributes an an abnormal extra-cellular matrix. Biochemical and mutational analysis for this disorder is available. Optimal surveillance of these patients, particularly for vascular adverse events, has not been determined.

## Therapy in the Classic, Hypermobility, and Vascular Types of Ehlers-Danlos Syndrome

There are no specific treatments for these forms of EDS. Supportive therapy, however, is essential for preservation of normal joint function and alleviation of joint pain. Planned exercise programs and muscle-strengthening exercises are useful and do much to maintain a positive outlook in these individuals, who may have a poor prognosis if joint stability and articular surfaces are compromised by excessive activity or chronic trauma. Unfortunately, many children and young adults with large joint hypermobility are attracted to activities such as gymnastics and dance, and these activities promote hypermobility and joint damage. The presence of multiple ecchymoses raises concern about a bleeding diathesis, particularly at the time of elective surgery. Although no consistent basis exists for the hemorrhagic tendency in the classic and hyperextensibility forms of EDS, anecdotally these patients tend to have higher blood losses than expected at surgery. In our center, we discourage pregnancy in patients with the vascular form, because the mortality rate is increased.

## Arthrochalasia Type

Formerly known as *EDS VIIA* and *VIIB*, this is an another autosomal dominant form of EDS resulting from mutations that cause faulty processing of type I collagen at the N-terminus.[93,94] EDS, arthrochalasia type, is characterized by pronounced and generalized joint hypermobility, moderate cutaneous elasticity, moderate bruising, a characteristic round facies with midface hypoplasia, and significant short stature. Their skin has a doughy feel and is fragile and hyperelastic. Kyphoscoliosis and muscle hypotonia are frequently present. These patients experience multiple dislocations, particularly involving large joints, including the hips, knees, and ankles. These dislocations often present in the newborn period, especially at the hips and ankles. Patients frequently need orthopedic surgery for their joint dislocation, and their tissues are highly friable, which complicates orthopedic procedures.

## Molecular Pathology

The two disorders (EDS VIIA and EDS VIIB), termed *arthrochalasia type*, result from mutations involving the N-terminal propeptide cleavage site of type I collagen. The arthrochalasia type of EDS has provided insight into the process of normal type I collagen fiber formation. The initial observation was of an accumulation of unprocessed

procollagen within the dermis of affected individuals.[95] With subsequent recognition that procollagen has both N- and C-terminal extension propeptides and that separate enzymes are responsible for their removal, the syndrome became more sharply defined as an accumulation of procollagen with the N-terminal peptides still attached (pN collagen).[96] Of the two distinctly different genetic abnormalities resulting in procollagen accumulation, the more frequent form is the mutational resistance of a procollagen cleavage site to the action of the N-terminal procollagen peptidase. The resistance results from an amino-acid substitution or deletion in the proCOL1A1 or pro2COL2A1chain (type VIIA and VIIB, respectively), leading to a portion of the collagen chains containing an abnormal N-terminal extension. This results from mutations in *COL1A1* or *COL1A2* in exon 6 of the molecule, which alters the proteinase cleavage site. Those individuals with mutations in exon 6 of *COL1A1* are more severely affected than those with similar mutations in *COL1A2*.

### Ehlers-Danlos Syndrome (Dermatosparaxis Type)

This type, dermosparaxix type, was formerly known as *EDS VIIC* and is an autosomal recessive form of EDS. In this type, the skin is extremely fragile, soft, and doughy, with easy bruising. The phenotype includes blue sclerae, marked joint hypermobility, micrognathia, large umbilical hernia, epiphyseal delay, and mild hirsuitism.[93] The dermosparaxix type results from a deficiency of the procollagen-N-propeptidase, in contrast to the arthrochalastic form, which involves the enzyme cleavage site and individuals have been identified who are homozygous form mutations in the gene,. Interestingly, this defect is homologous to the defect in sheep and cattle termed *dermatosparaxis*.[97]

### Ehlers-Danlos Syndrome (Kyphoscoliosis Type)

This type of EDS, kyphoscoliosis type, formerly known as *EDS VI*, is inherited as an autosomal recessive disease. The findings in this disorder include severe kyphoscoliosis, noted-at-birth recurrent joint dislocations, hyperextensible skin and joints, poor tone, and reduced muscle mass.[98] The skin is grossly abnormal, and has been described as pale, translucent, velvety and, upon trauma, showing gaping wounds that heal poorly. One difference in this form of EDS is that there is significant ocular involvement. Affected individuals have microcornea, retinal detachment, and glaucoma leading to blindness in some individuals. In addition, respiratory and cardiac compromise and, ultimately, cardiorespiratory failure may develop in patients with severe kyphoscoliosis.

#### Molecular Pathology

This disorder results from lysyl hydroxylase deficiency.[99] A variety of mutations within the lysyl hydroxylase gene have been defined and include premature stop codons, amino-acid substitutions, internal deletions, and compound heterozygotes.[99] Defective lysyl hydroxylase impairs the conversion of lysyl residues to hydroxylysine on procollagen peptides. The consequence of deficient hydroxylysine content of collagen is the effect it has on cross-linking, which helps stabilize the mature collagen molecule.

### Other Ehlers-Danlos Syndrome Types

There are numerous other rare forms of EDS that have some overlap with other disorders or have only been reported in a small cohort of individuals, and thus will not be included in the discussion.

## MARFAN SYNDROME

One of the most common inherited disorders of connective tissue, Marfan syndrome (MFS) is an autosomal dominant disorder with a reported incidence of 1 in 10,000 to 20,000 individuals.[100] There is a wide spectrum of clinical presentations, from the severe infantile form to individuals who are only mildly affected. Although the most impressive findings are relative to the musculoskeletal, cardiac, and ocular findings, affected individuals also suffer from pulmonary, neurologic, and psychological complications. Marfan syndrome has also become one of the few genetic disorders for which there has been advocacy for treatment to slow the progression of the disease. Physicians need to recognize the phenotype because many of the affected individuals are seen with life-threatening emergencies.

### Clinical Features

Marfan syndrome can be difficult to diagnose in some individuals and families, and it also has been recognized that it has been overdiagnosed. Stringent criteria for this diagnosis were proposed in 1996 and revised in 2010.[100] The 1996 criteria rely on the recognition of both "major" and "minor" clinical manifestations involving the skeletal, cardiovascular, dura, and ocular systems. Major criteria include four of eight typical skeletal manifestation and ectopia lentis, aortic root dilatation involving the sinuses of Valsalva or aortic dissection, and lumbosacral dural ectasia by computed tomography (CT) or MRI. Major criteria for establishing the diagnosis in a family member include having a parent, child, or sibling who meets a major criterion independently, the presence of a *FBN1* mutation. To unequivocally establish the diagnosis in the absence of a family history requires a major manifestation from two systems and involvement of a third system. If a mutation known to cause MFS is identified, the diagnosis requires one major criterion and involvement of a second organ system. The reason for this is that there is a great deal of intrafamilial variability in this disorder, and there are individuals who harbor heterozygosity for mutations, yet do not meet criteria for Marfan syndrome and may have different prognoses.[101] Similar to other connective tissue disorders, there is wide variability in phenotypic expression.

Aortic disease leading to the formation of aneurismal dilatation and dissection is the main cause of morbidity and mortality in the MFS.[101] Dilatation of the aorta is found in 50% of children and progresses with time. Echocardiography demonstrates that 60% to 80% of adult patients have dilatation of the aortic root that may involve other segments of the thoracic aorta, the abdominal aorta, or even

the carotid and intracranial arteries. Dissection usually begins above the coronary ostia and extends the entire length of the aorta. Of patients with MFS, 60% to 70% have mitral valve prolapse with regurgitation. Heart failure and myocardial infarction may complicate the course of patients with MSF. Pregnant women are at particular risk for aortic dissection, particularly those who already have aortic root dilatation; this should be taken into consideration when treating women of reproductive age with MFS.[102]

Arachnodactyly occurs in 90% of patients. Listed below are techniques that aid in determining arachnodactyly.

- The thumb. The Steinberg test is positive when the thumb, enclosed in the clenched fist, extends beyond the hypothenar border.
- The wrist. The Walker-Murdoch sign is positive when there is overlap of the thumb and fifth digit when they encircle the opposite wrist.
- The metacarpal. The metacarpal index is done by radiographic determination and is the mean value of the lengths divided by the midpoint widths of the second, third, and fourth metacarpals. In healthy patients, the metacarpal index ranges from 5.4 to 7.9, whereas this range is 8.4 to 10.4 in patients with MFS.

Thoracic kyphosis may be associated with reduced lung capacity and residual volume that may lead to pulmonary insufficiency. Dural ectasia, which may occur in as many as 40% of patients, results from enlargement of the spinal canal caused by progressive ectasia of the dura and neural foramina and erosion of vertebral bone. This usually involves the lower spine.[103] Diminished BMD has been reported in several patients with MFS.[104] Ectopia lentis occurs in 50% to 80% of patients with MFS. Subluxation of the lens is usually bilateral and appears by the age of 5 years. Although the lens is typically displaced upward, displacement into any quadrant may occur. Visual acuity is diminished in many patients because of lens subluxation or secondary acute glaucoma. Secondary myopia, retinal detachment, and iritis with loss of vision contribute to most of the ocular-related morbidity.[105]

Large epidural venous plexuses in the lumbar and cervical regions have been found to develop in patients with MFS, a major diagnostic criterion for the syndrome. These engorged venous plexuses, which are visualized by MRI myelography have, in turn, been associated with the syndrome of spontaneous intracranial hypotension, which is also associated with dural tears. Clinical signs of this are severe headache, back and leg pain, radiculopathies, and incontinence secondary to cerebral displacement. Spinal abnormalities in MFS include increased interpedicle distance of nonrotated vertebrae, vertebral inversion (flattening of the normal kyphosis at the dorsal level and kyphosis or disappearance of the physiologic lordosis at the lumbar level), and vertebral dysplasia (dolichospondylia, elongated vertebral bodies with increased concavity). Scoliosis constitutes one of the major management problems in MFS. In one series, the average age of onset was 10.5 years (range of 3 to 15 years), with rapid progression during adolescence. If mechanical bracing or physical therapy fails to halt progression, spinal fusion should be considered, particularly when the curvature exceeds 45 to 50 degrees.[106,107]

## Differential Diagnosis

### Homocystinuria

Homocystinuria, which shares several skeletal and ocular features with MFS, is the prime diagnostic consideration.[108] This is an autosomal recessive disease. The characteristic features of this metabolic disorder of sulfur metabolism are marfanoid phenotype with joint laxity, scoliosis, lens dislocation, early-onset osteoporosis, vascular thrombosis affecting arteries and veins due to increased clotting activity and the cytotoxic effect of homocysteine on vascular endothelial cells, and mild mental retardation.[108]

Cystathionine β-synthase (CBS) deficiency is the most common cause of homocystinuria.[108] Affected individuals have elevated levels of homocystine and methionine levels, whereas cystathionine and cysteine levels in blood are decreased. Importantly, this disorder is differentiated from MFS because the direction of ectopia lentis is different than MFS and there is no progressive aortic root dilation.

## Molecular Biology of Marfan Syndrome

Fibrillin 1 (FBN1) protein is an important component of both elastic and nonelastic connective tissues throughout the body.[109] It is the main protein of a group of connective tissue microfibrils that are essential for normal elastic fibrillogenesis. In nonelastic tissues, the FBN1-containing microfibril functions as an anchoring fiber. *FBN1* is a large gene (65 exons).

*FBN1* mutations occur across a wide range of milder phenotypes that overlap the classic Marfan phenotype, including dominantly inherited ectopia lentis, Shprintzen-Goldberg syndrome, acromicric dysplasia, Weill-Marchesani syndrome, and familial or isolated forms of aortic aneurysms.[110-115] The majority of these are private mutations (occur genetically independent with no "hot spot" in the molecule). The one exception is the rare infantile MFS mutations, which cluster between exons 24 and 26 and exon 32.[116] Heterozygosity for missense, frameshifts, deletions and insertions, splice site alterations, and nonsense mutations have all been seen.[117] The clinical presentation of the fibrillinopathies caused by *FBN1* mutations range from isolated ectopia lentis, to short stature in acromicric dysplasia, to severe neonatal MFS, which generally leads to death within the first 2 years of life

## Treatment

In 1972, the life span of untreated patients with classic MFS was approximately 32 years. The early mortality in the MFS results primarily from complications associated with aortic dilatation. This symmetric dilatation of the sinuses of Valsalva is progressive throughout life and is often detectable in infancy. In the early 1970s, it was suggested that perhaps treatment and surveillance could lessen the complications of aortic dissection in MFS. There have been many treatment trials with β-blockers. When compared with the control group, the treated individuals had a significantly slower rate of dilatation of the aortic root, improved survival, and fewer treated patients reached a clinical end point (death, congestive heart failure, aortic regurgitation, aortic dissection, or cardiovascular surgery).[118,119]

Data generated from mouse models of MFS suggest excessive signaling by the transforming growth factor (TGF)-β family of cytokines.[120] A large randomized control trial on these findings suggested that losartan, an antihypertensive, and an angiotensin II blocker would have advantages over β-blocker use because it can attenuate TGF-β signaling. A randomized control study in MFS using atenolol versus losartan did not show any difference between the two drugs.[121]

Echocardiograms are the mainstay of management for the aortic root complications of MFS. Elective repair of aortic root disease before enlargement to 4.5 cm is typically suggested and is preferable to emergency repair required for marked dilatation or dissection.[122] Mitral valve replacement is frequently accomplished during the same procedure. Most importantly, repeated trials have shown that patients who undergo elective repair versus emergent repair do substantially better.

Correction of scoliosis may be attempted with bracing; however, surgical repair should be considered when the curve exceeds 40 degrees. Progressive scoliosis in MFS may require fixation with rods, and complications of joint laxity may require orthopedic correction. Arthropathy associated with excessive joint mobility may require orthopedic intervention. Dislocated lenses should not be removed surgically unless more conventional means of correcting vision are ineffective.

## LOEYS-DIETZ SYNDROME

In 2005, individuals with a previously undescribed autosomal dominant aortic aneurysm syndrome were described.[123] This disorder, now referred to as *Loeys-Dietz syndrome*, is also characterized by hypertelorism, bifid uvula and/or cleft palate, and generalized arterial tortuosity with ascending aortic aneurysm and dissection. Other abnormal findings include craniosynostosis, structural brain abnormalities, mental retardation, congenital heart disease, and aneurysms with dissection throughout the arterial tree.

Some individuals with Loeys-Dietz syndrome have a clinical phenotype that overlaps with MFS, but none met diagnostic criteria set forth. Although MFS is associated with progressive arterial disease, in Loeys-Dietz syndrome, the aneurysms tend to be particularly aggressive and rupture at an earlier stage and size than seen in MFS.[123] Heterozygosity for mutations in *TGFBR1*, *TGFBR2*, *TGFB2*, and *SMAD3* have been identified.[123-125] From a management perspective, it is important to recognize these individuals because they are managed more aggressively than in MFS.[126] Aortic aneurysms are corrected at smaller sizes (4 cm), and complaints such as abdominal pain and headaches should be thoroughly investigated because they may be associated with aneurysms. The distinction from MFS is important because the management needs to be even more aggressive.

## CONGENITAL CONTRACTURAL ARACHNODACTYLY

Congenital contractural arachnodactyly is an autosomal dominant condition that includes tall stature, arachnodactyly, dolichostenomelia, and multiple contractures involving large joints.[127] There is a characteristic "crumpled ear" deformity caused by a flattened helix with partial obliteration of the concha. Marked deformity of the chest cage also occurs, and scoliosis may be progressive and severe. For unknown reasons, the contractures tend to become less severe with age. Radiographically, osteopenia can be seen. The ocular and typical cardiac lesions of classic MFS are absent. This disorders result from heterozygosity for mutation in *FBN2*.[127]

## CONCLUSION

The heritable disorders of connective tissues are a heterogenous group of disorders characterized by abnormalities in skeletal tissues, which include cartilage, bone, tendon, ligament, muscle and skin. They are fascinating because the clinical spectrum ranges from extreme short stature to excessively tall individuals, and the types of altered genes span all numerous gene families and pathways. Affected individuals usually need medical attention their entire lives and, unfortunately, have been victims of appearing different because they cannot mask their abnormalities. Understanding and appreciation for the unique set of medical issues in each disorder will hopefully improve these individuals' quality of life and their life span.

PART 16 RHEUMATIC DISEASES OF CHILDHOOD

CHAPTER 106

# Etiology and Pathogenesis of Juvenile Idiopathic Arthritis

Lucy R. Wedderburn • David Bending • Kiran Nistala

**KEY POINTS**

- **Juvenile idiopathic arthritis (JIA) is a group of conditions with distinct clinical phenotypes and, likely, differing underlying pathogenic mechanisms.**
- **The heterogeneity of JIA at pathologic and immunologic levels is informative in driving our understanding of these diseases.**
- **An increasing number of genetic regions, outside of the major histocompatibility complex (MHC), have been linked to JIA. The majority of confirmed genetic hits are polymorphisms lying outside of coding DNA, many of them in enhancer regions.**
- **In JIA there is evidence to support abnormalities in both innate and adaptive immune systems. Successful treatments may require targeting of multiple cytokine pathways in a single patient.**
- **Strong links with MHC loci, threshold and signaling pathways, and the presence of inflammatory T cells within the inflamed joint supports a role for T cells in the pathogenesis of JIA.**
- **Systemic arthritis has an immune profile distinct from other types of JIA. Inflammatory mediators of the innate immune system, including IL-1β, IL-6, and myeloid-related protein, play a major role in disease pathogenesis.**

Juvenile idiopathic arthritis (JIA) is a heterogeneous group of diseases that lead to a final common pathway: thickening and inflammation of the joint lining (or synovium membrane). Infiltrating inflammatory cells interact with each other and resident synovial fibroblasts, promoting a chronic inflammatory process in the synovial membrane and secreted synovial fluid (Figure 106-1). In this chapter, we discuss the genetic factors that predispose to JIA and the abnormalities that underlie synovial and systemic inflammation. As well as the established association between the major histocompatibility complex (MHC) loci and JIA, more recent studies have detected links to genes that regulate cellular activation, signaling thresholds, or cytokines.[1,2] The fact that immune-related genes make up the major risk alleles in JIA strongly supports the concept of JIA as a disease of dysregulated immunity.

Highly activated T cells, monocytes, and neutrophils are attracted to joints and secrete mediators that perpetuate inflammation and attenuate immune regulation. The relative importance of individual cytokines varies among disease subtypes. Results from therapeutic trials support a role for TNF in the pathology of polyarthritis forms of JIA, and IL-1β and IL-6 in systemic JIA (sJIA), as well as some patients with polyarticular JIA (Table 106-1). The last decade has seen a step change in the quality of treatments in JIA. To build upon this success, we need to be able to interrogate the vast array of biologic data that is emerging in field of JIA, and translate this knowledge into novel therapies and a more tailored treatment approach for our patients.

The term *juvenile idiopathic arthritis* refers not to one disease but to a group of conditions, defined under the International League of Associations for Rheumatology (ILAR) classification, which have the common features of beginning before the sixteenth birthday and characterized by arthritis of at least one joint that persists for 6 weeks or more.[3] Although this classification has proven highly valuable for both clinical and basic research, and has enabled more precisely defined subgroups and comparison of data from different studies, it does not encompass all aspects of the heterogeneity of childhood arthritis. Thus, for example, use of the classification criteria with strict exclusion rules may lead to as many as 30% of cases designated as "unclassified." In addition, certain common features may occur across several subtypes. For example, factors associated with risk of autoimmune uveitis of JIA include positivity of the anti-nuclear antibody (ANA), early age at onset, and female sex. Girls with young-age onset of arthritis and ANA positivity represent a group of patients who have been proposed to represent a relatively homogeneous group yet currently may fall into several subtypes within the ILAR classification.[4] Similarly, genes and immunologic processes that influence the likelihood of mild oligoarthritis to extend to more severe arthritis may well overlap with etiopathologic factors involved in polyarticular JIA.[5,6] Furthermore, an increasing understanding of the pathogenesis of systemic-onset JIA has led to the suggestion that this condition may be more akin to an autoinflammatory disorder and should perhaps be classified separately.[7] In the future, a full molecular and genetic analysis of the heterogeneity of childhood arthritis may permit the development of a more mechanism-driven classification, which could help inform on disease course, complications, or response to treatment.

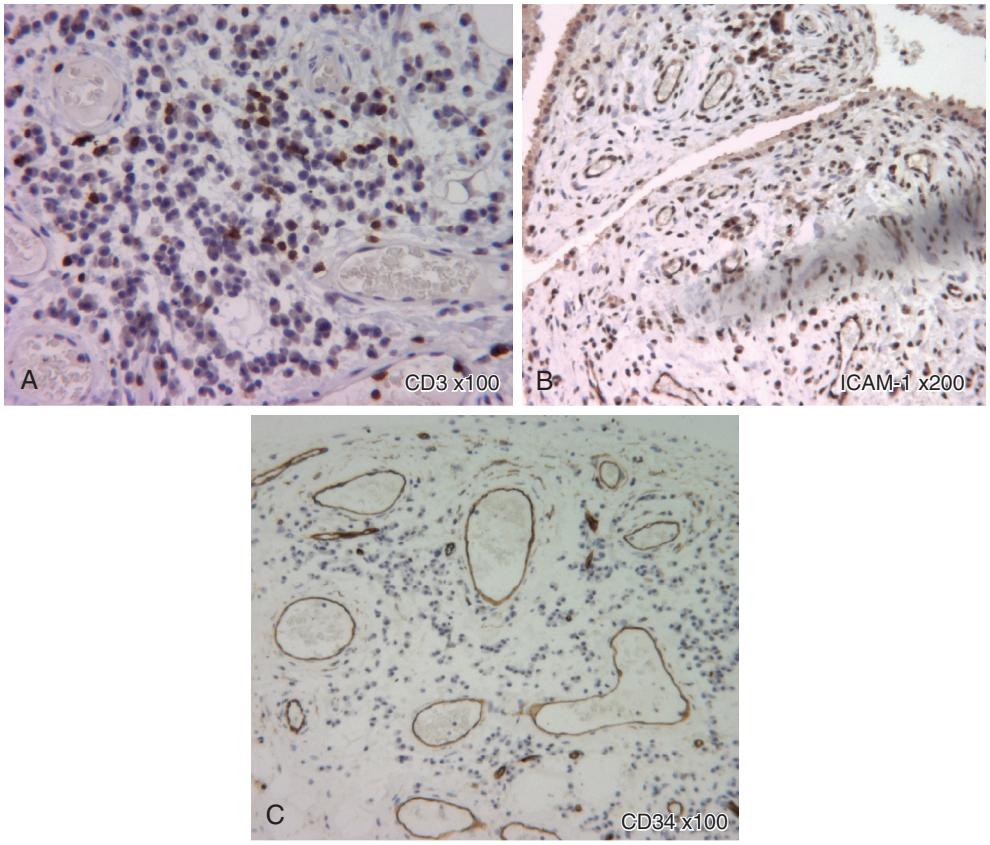

**Figure 106-1** Sections of synovium from the knee of a child with oligoarticular juvenile idiopathic arthritis showing intense inflammatory infiltrate and highly vascular hypertrophied tissue. **A,** Stained for CD3 (surface protein on T lymphocytes) (magnification, ×100). **B,** Stained for intra-cellular adhesion molecule 1, which is expressed on the endothelium and a proportion of the infiltrating cells (magnification, ×200). **C,** Stained for CD34, expressed on vascular endothelium (and hematopoietic stem cells) (magnification, ×100).

**TABLE 106-1** Summary of Cytokines and Inflammatory Mediators Implicated in Juvenile Idiopathic Arthritis

| Cytokine/ Mediator | Cell | Pathology |
|---|---|---|
| TNF | Monocytes, T, B cells, PMNs, mast cells, fibroblasts | Activates monocytes and neutrophils<br>Damages cartilage<br>↑Endothelial cell adhesion molecules<br>Inhibits regulatory T cells |
| IL-1β | Monocytes, B cells, fibroblasts | Activates osteoclasts (bone damage)<br>Fibroblast cytokine, chemokine release<br>↑Endothelial cell adhesion molecules |
| IL-17 | T cells (Th17), mast cells | Chemokine release (recruit PMNs)<br>Cartilage damage<br>Activates osteoclasts<br>Synergizes with TNF and IL-1β |
| IL-6 | Monocytes, fibroblasts, B cells | B cell activation<br>Inhibits regulatory T cells<br>Growth retardation<br>Acute phase response and anemia |
| IFN-γ | T cells ($CD4^+$ Th1, $CD8^+$, NK cells) | Activates monocytes<br>↑Endothelial cell adhesion molecules<br>May assist recruitment of Th17 cells |
| MRP 8/14 | Monocytes, PMNs | Activates monocytes<br>Promotes pathologic $CD8^+$ T cells<br>Secretion of IL-1β<br>↑Endothelial cell adhesion molecules |

IFN-γ, Interferon-γ; IL, interleukin; MRP, myeloid-related protein; NK, natural killer; PMNs, polymorphonuclear neutrophils; TNF, tumor necrosis factor.

Both genetic and environmental factors, as well as the manifestations of their interactions through inflammatory and immunologic mechanisms, are clearly implicated in the pathogenesis of JIA. Recent advances in our understanding of some clinical subtypes, most notably systemic JIA, have led to specific and distinct features being recently recognized that have led to novel treatment options. However, it is also increasingly clear that some underlying genetic risk associations and immune abnormalities may have effects across several types of childhood arthritis and, indeed, across many forms of autoimmune disease.

## HISTOLOGIC FEATURES OF SYNOVIUM IN JUVENILE IDIOPATHIC ARTHRITIS

The pathologic hallmark of juvenile inflammatory arthritis is the inflamed synovium. Histology of this tissue shows thickened synovium that is highly vascular and shows marked hyperplasia of synoviocytes in the lining layer, as well as a dense infiltrate of inflammatory cells comprising T cells, macrophages, dendritic cells and, in some cases, B cells and natural killer (NK) cells[8,9] (see Figure 106-1). The hypertrophied synovial layer is highly vascular and likely related to the increased production of proangiogenic factors, including vascular endothelial growth factor (VEGF), osteopontin, and the angiogenic chemokines,[10-12] whereas recruitment of the inflammatory infiltrate is likely mediated by multiple chemokines that are increased in JIA, including

CCL5, CXCL10, CCL20, IL-8, and membrane cofactor protein (MCP)-1, among others.[13,14] The proteolytic enzymes, matrix metalloproteinases (MMP)-1 and MMP-3, are abundantly expressed in synovial lining, and their levels correlate with degree of infiltration, in particular by myeloid $CD68^+$ cells.[14] The T cells that infiltrate the inflamed synovium, like those in the excess synovial fluid, are highly activated memory cells[15,16] of both CD4 and CD8 populations.[17]

## Genetics of Juvenile Idiopathic Arthritis

**KEY POINTS**

- There is strong evidence for a genetic component to the etiology of JIA.
- The strongest genetic associations of JIA are with genes of MHC.
- Specific class I MHC alleles are associated with enthesitis-related arthritis.
- Distinct class II MHC alleles are associated with oligoarthritis and polyarthritis subtypes.
- Many genes that alter the threshold of immune cell activation and signaling, or relate to cytokines and their receptors, are linked with JIA.
- Recent evidence suggests that many of the genetic differences associated with JIA fall in enhancer regions that affect gene expression rather than in coding sequences.

There is strong evidence for a genetic component to the etiology of the JIA diseases. Twin studies have shown concordance rates in monozygotic twins of between 20% and 40%.[18] A study of 164 affected sibling pairs with JIA showed a 70% concordance for gender, 73% for age at disease onset, and 66% for disease course.[19] Estimates suggest that the recurrence risk for siblings of a proband with JIA are between 15 and 30 times that of the general pediatric population, a figure that is as high as for insulin-dependent diabetes mellitus (IDDM) or multiple sclerosis.[20] In addition, first-degree relatives of children with JIA have a higher rate of other autoimmune disease than controls.[21] Despite this, families of multiple affected siblings are rare. One caveat in comparing early studies is that some were performed using the American College of Rheumatology (ACR) classification criteria (at that time called *JRA*), and so may not be directly comparable to studies that have used the ILAR classification of JIA.

Genetic influences on JIA susceptibility and phenotype are polygenic so that JIA is thought of as a complex genetic trait.[2,20] Although some studies have analyzed all forms of JIA together, the heterogeneity of childhood arthritis suggests distinct genetic risk associations for different phenotypes; this has been confirmed in recent adequately powered studies. The strongest genetic associations with JIA are of genes that lie within the MHC or human leukocyte antigen (HLA). These were the first to be documented as associated with childhood arthritis.[22] The MHC region, located on chromosome 6 of the human genome, includes more than 200 genes, many of which are central to functions of the immune system. Numerous associations between HLA genes and JIA have been reported, and these involve many different populations.[2,23] The best characterized associations are with genes of the class I and class II MHC loci, genes that code for heterodimeric proteins that present peptide antigen to the specific antigen receptor of T cells (the TCR).

Class I loci include HLA-A, -B, and -C, of which the earliest report was of the association between HLA-B27 and the form of JIA known as *enthesitis-related arthritis* (ERA), which includes children whose disease has parallels with adult ankylosing spondylitis (AS) (see Chapters 74 and 75). The HLA-A2 allele *HLA-A*0201* is increased in several types of JIA, especially oligoarthritis and children with early-age onset.[24,25]

Multiple studies have revealed associations of class II MHC loci, (HLA-DR, -DP, and -DQ), with JIA, of which the strongest are DRB1*0801 and *11 with oligoarticular JIA, as well as DRB1*1301, in particular in $ANA^+$ cases.[25] Because of inheritance of genes in the MHC region together in haplotypes because of linkage disequilibrium (LD), observed associations may in fact be the result of genes within the haplotype, distinct from the locus first implicated. Several haplotypes across the MHC confer increased risk for all types of JIA, such as DRB1*08-DQA1*0401-DQB1*0402, which confers an odds ratio of 6.1 and 10.3 for persistent and extended oligoarticular JIA, respectively. Frequency of the DRB1*1301-DQA1*01-DQB1*06 haplotype distinguishes persistent from extended oligoarticular JIA, whereas DRB1*0801 and *1401 are associated with polyarticular JIA.[25] Some associations closely mirror those of the corresponding adult disease, such as the strong association of the HLA-B27 allele with spondyloarthropathy and the HLA-DRB1*0401 allele with rheumatoid factor $(RF)^+$ polyarticular JIA. Although sJIA shows less strong associations with HLA alleles, even in this subtype, specific haplotypes (such as DRB1*11-DQA1*05-DQB1*03) are increased compared with control participants. A study with fine allele-specific typing across eight HLA loci in a large cohort and analyzing by haplotype, confirmed that within class II loci, HLA-DR is the driving association, rather than HLA-DP.[26] Some HLA allele/JIA subtype associations show[24] age-specific effects, in that they confer risk over a specific age range only. Another study confirmed both age- and gender-specific effects.[26] Thus, for example, in polyarticular JIA the HLA-DRB1*0801 allele has risk effect in those who are older than 6 years when their arthritis begins, whereas in younger-onset polyarticular JIA, the risk alleles are more closely related to those of patients with oligoarticular JIA: HLAB1*1103/1104. Some HLA alleles, notably DRB1*0401, *0701, and *1501, are consistently reduced in frequency in JIA cases compared with controls, suggesting a protective effect for some or even all subtypes. These associations among genes that code for proteins, the central function of which is the presentation of antigenic peptides to T cells, implicate a T cell–driven process in at least part of the etiopathogenesis of JIA.

In addition to genes coding for MHC proteins, a large number of other candidate genes (now totaling more than 100) have been the focus of research in JIA.[2,27] Inflammatory cytokines have been an important target for drug development in JIA, and their gene polymorphisms have been an area of scrutiny. Genes studied have included cytokine

and chemokine genes such as those for IL-1, IL-6, TNF, macrophage inhibitory factor (MIF), IL-10, and their receptors (including IL-1R, IL-2RA, CCR5), and key signaling molecules, including CTLA4 and PTPN22. However, only a few of these loci have been independently validated in candidate gene studies. These include genes for the PTPN22, MIF, SLC11A6, WISP3, and TNF and, in a meta-analysis, CCR5, proteins.[28]

Genetic association at the TNF locus is complex to study, given the position of the TNF locus within the MHC, but some data suggest that several specific TNF haplotypes are significantly associated with JIA, although the functional consequences of these alleles are not yet clear.[29] The hypothesis suggesting a link between sJIA and IL-6 was proposed many years ago because several clinical features in sJIA resembled the phenotype of IL-6 overexpression (e.g., fevers, stunted growth, anemia).[30,31] A polymorphism (−174G/C) in the regulatory region of the IL-6 gene alters transcription of IL-6 in response to IL-1 and lipopolysaccharide; sJIA patients have significantly lower frequency of the protective CC genotype, and the IL-6 −174G allele has been confirmed as a susceptibility gene for sJIA.[32,33]

Some conflicting studies on candidate gene loci reflect two problems that hindered progress: the heterogeneity of JIA, which means that combining all JIA into one study may lead to loss of detection of effects specific for a subtype, and, opposing this, the difficulty of reaching adequate power for genetic studies, if stratification by subtype is preferred. New insights have come from several large genetic studies. The Wellcome Trust Case Control Consortium performed genome-wide association studies in seven major common diseases, including rheumatoid arthritis (RA).[34] Extrapolation of loci implicated in RA to JIA has suggested that other key loci associated with JIA are IL-2/IL-21 and IL-2RA, the alpha chain of the IL-2 receptor, also known as *CD25*.[35,36] Another study focused upon specific subtypes of JIA and comparison with their adult disease counterparts. The genetic loci IL-23R and endoplasmic reticulum aminopeptidase-1 (ERAP1) have been identified as carrying risk associations with ankylosing spondylitis and psoriatic arthritis in adults.[37] Genotyping of these genes in a large cohort of JIA cases has shown associations of both with the ERA subtype of JIA but no association with JIA as a whole, again emphasizing subtype-specific genetic features and, likely, pathogenesis.[38] ERAP1 is of particular interest given its functional role in trimming of peptides within the ER, for presentation of peptide on, and folding of, class I MHC molecules,[39] and given the strong evidence for class I MHC folding abnormalities in patients with the HLA-B27 risk alleles (HLA-B*2705 and *2702, among others). ERAP1 is also thought to have a role in trimming of cytokine receptors at the cell surface. IL-23 is of great functional interest because of the central role of IL-23 in the Th17 pathways and the demonstration that Th17 cells play a role both in JIA and adult AS and psoriatic arthritis.

Significant insights into the pathogenesis of childhood arthritis have been gained by the largest ever genetic study to date on approximately 3000 JIA oligoarticular and polyarticular RF-JIA cases by using the Immunochip (Illumina, San Diego) platform. This provides single nucleotide polymorphism (SNP) genotyping of 186 known autoimmune loci. The study confirmed a total of 16 non-HLA loci as associated with JIA at genome-wide significance level.[40] New analysis modeling the most likely causal SNPs, and linking both genetic and epigenetic data, in JIA and other autoimmune diseases, has suggested that true causal SNPs frequently fall in enhancer or super enhancer regions that regulate gene expression.[41]

## ADAPTIVE IMMUNE SYSTEM

**KEY POINTS**

- **Effector T cells secreting pro-inflammatory cytokines are enriched in the joint membrane and synovial fluid.**
- **Regulatory T cells are found in the joints of JIA patients and are enriched in persistent oligoarthritis patients; however, they can have an atypical phenotype in synovial fluid.**
- **Immune regulation may be impaired as a result of cytokine-driven resistance of effector T cells to suppression.**
- **A B cell gene expression signature has been detected in the peripheral blood of patients with an early age at onset of JIA.**

### T Cells

The strong association of many JIA subtypes with genetic variants at HLA loci, as well as the central role of HLA proteins in presenting peptide antigens to T cells for recognition, which is central to T cell function, has led to intense investigation of the role of T cells in the pathology of JIA. Highly activated memory T cells make up a significant proportion of the inflammatory infiltrate in JIA, and express an "oligoclonal" or restricted set of TCRs.[17,42] Specific T cell clones can be long lived, and are detectable in different inflamed joints. Nevertheless, it is still unclear whether these clones represent autoreactive T cells specific for an "arthritogenic" self-epitope. Although immune activation leads to tissue damage in JIA, the role of self-antigen recognition in this process remains unclear. Recent probing of autoreactive T cells in a mouse model of arthritis identified a ubiquitously expressed ribosomal protein, RPL23A, as an autoantigen to which T cells and antibodies from rheumatoid arthritis patients could also react.[43] However, to date, no clear autoantigens have been identified in JIA. The association of JIA with genetic loci that influence the threshold of T cell activation, such as PTPN22,[44] cytokine receptors essential to T cell biology (IL-2RA, IL-2RB), as well as those central to recognition of antigen by T cells (HLA), supports the concept of JIA as a disease of dysregulated adaptive immunity.

Early work examining animal models of arthritis suggest that cells of the T helper (Th)1 lineage, secreting IFN-γ, are central to pathogenesis. Th1 cells are recruited to the joint by high levels of chemokines CCL5, MIP-1a, and IP-10,[45] and make up the majority of T cells in the JIA joint.[15] However, in both mouse models of arthritis and early clinical trials, blocking IFN-γ offered little clinical benefit, suggesting that other players may be more important to pathogenicity. TNF, the prototypic inflammatory cytokine in arthritis, is secreted by T cells and macrophages within the JIA joint and is detectable within inflamed synovial tissue,[46] and, to a lesser extent, in synovial fluid.[47] The success of TNF blockade in polyarthritis and extended

oligoarthritis subtypes implicates TNF in JIA pathology, but its mechanisms of action remain unclear. Some evidence suggests that TNF inhibitor therapy can improve the response of effector T cells to suppression by regulatory T cells, suggesting TNF may be pathologic because of its ability to impair regulation at the inflamed site.[48] Still, roughly 30% of patients do not respond adequately or relapse on TNF inhibitor therapy and the Th17 T cell population. Secretion of IL-17 and IL-22 may in part account for this recalcitrant disease.[49] IL-17 causes significant bony and cartilage damage in the joint by promoting neutrophil influx via the secretion of IL-8 and synergizing with IL-1β and TNF to drive metalloproteinase secretion and osteoclast activation. Th17 cells are enriched in the joints of JIA patients, and Th17 numbers correlate with severity of disease course in oligoarthritis.[14] Th17 cells within the JIA joint can also upregulate expression of granulocyte-monocyte colony-stimulating factor (GM-CSF).[50] Because both IL-17 and GM-CSF are potent inflammatory cytokines that are pathogenic in mouse models of autoimmunity,[51] this raises the hope that Th17 or GM-CSF blockade may be an effective treatment in some subtypes of JIA.

In addition to pro-inflammatory processes, there is strong evidence for ongoing immune regulation in JIA. *IL2RA*, the gene encoding CD25, and *RUNX1*, a transcription factor that interacts with FOXP3, are two genes intimately involved in regulatory T cell (Treg) biology that are significantly associated with JIA.[40] Children with persistent oligoarticular JIA have high numbers of Treg cells expressing CD25 and FOXP3 within the joint, and these are significantly higher than those with more severe extended oligoarticular disease.[52,53] In addition, $CD30^+$ T cells specific for the conserved self-antigens heat shock proteins (HSP) appear to play a regulatory role.[54]

Although synovial Treg cells suppress effector T cell functions in vitro, inflammatory cytokines such as IL-6 and TNF, present in the arthritic joint, may attenuate Treg cell function in vivo.[48,55] In addition, Treg cells in synovial fluid can have an atypical phenotype with low to absent expression of FOXP3, which is associated with defects in pathways that control FOXP3 expression.[56] Furthermore, some Treg cells expressing the innate lymphoid cell marker CD161 can secrete inflammatory cytokines, suggesting that perturbation of the Treg compartment may occur in JIA.[57] Treatment strategies that expand Treg cell numbers and augment function are currently under investigation[58,59] will need to take into account issues of Treg cell stability and their potential for pro-inflammatory phenotype.

## Antigen-Presenting Cells

Dendritic cells are specialized antigen-presenting cells (APCs) that activate T cells, as well as promote the differentiation of effector T cell functions. Comparatively little is known about their role in JIA. In the inflamed joint, myeloid dendritic cells (mDCs) are localized to the synovial lining layer, whereas IFN-α–secreting plasmacytoid dendritic cells (pDCs) are in T and B cell–rich aggregates.[47] Both subsets are found in high numbers within synovial fluid when compared with PB. Synovial mDC express high levels of co-stimulatory molecules, including CD80, CD86, and receptor activator of NF-κB (RANK),[60,61] which augment T cell activation and lead to the secretion of pro-inflammatory cytokines and chemokines. In contrast to mDCs, some studies suggest that synovial pDCs may provide a regulatory function. pDCs within the joint do express markers of activation,[62] but secrete high levels of granzyme B, which limits T cell proliferation.[63]

## B Cells

There has been a renewed interest in B cell–effector function in inflammatory arthritis following the efficacy of the anti-CD20 agent rituximab in RA. In JIA, the exact role of B cells as effector or regulatory players is still unclear. B cell–derived autoantibodies, ANAs, RFs, and anti-citrullinated protein antibodies (ACPAs) are common in some JIA subtypes, but none are considered to be directly pathogenic (see Chapter 107). Interestingly, patients who are $ANA^+$ are more likely to have T-B cell aggregates in their synovial membrane, suggesting a link between lymphoid neogenesis and autoantibody production.[64] Although lymphoid aggregates are seen in JIA synovium, mature germinal centers are rare compared with RA. B cells only make up small fraction of mononuclear cells within synovial fluid, but are skewed toward a memory phenotype, expressing high levels of the co-stimulatory molecules CD80 and CD86.[65] When cultured together with T cells in vitro, synovial B cells were more likely to activate T cells toward a Th1 phenotype than equivalent peripheral B cells.[66] Total B cell numbers do not vary between JIA patients and healthy controls, but oligoarthritis patients have higher numbers of immature transitional-type B cells in their blood compared with healthy controls (CD38 high, CD24 high).[65] However, treatment with methotrexate reduced the frequency of this immature population, whereas etanercept had no effect on B cell subsets.[67] Patients with an early onset of disease also have expression of B cell and immunoglobulin-related genes in peripheral blood.[68] The B cell signature, as well as frequent ANA positivity in patients with oligoarthritis, has led some authors to suggest a major role for B cells in the pathogenesis of this subtype.

## Innate Immune System

**KEY POINTS**

**Defects in the innate immune system have been most closely associated with sJIA.**

**Neutrophils and monocytes secrete myeloid-related protein 8/14, IL-6, IL-1β, and TNF, which drive systemic inflammation.**

Many cytokines detectable in the inflamed joint are the products of the innate immune system. The successful targeting of these cytokines with biologic agents (e.g., IL-1β and IL-6) heavily implicates the innate immune system in the pathology of JIA, particularly the sJIA subtype.

### Macrophages/Monocytes

Monocytes and their tissue counterparts, macrophages, are key effector cells of the innate immune system and have been linked to the pathogenesis of autoimmune arthritis for several decades.[69] In JIA, analysis of gene expression has

detected an activated macrophage gene expression signature in the cells within synovial fluid of early oligoarthritis patient at risk of extension[70] and a monocyte signature in the peripheral blood of patients with an older-onset oligoarthritis,[68] and RF+ polyarthritis patients.[71] Monocytes typically make up equivalent proportions of synovial fluid and peripheral blood mononuclear cells (approximately 10%), but they have a highly activated phenotype,[70] secreting high levels of IL-6, IL-1β, and TNF within the joint.[72] Synovial monocytes also secrete VEGF and osteopontin (OPN), which contribute to the vascularity of inflamed pannus,[73] and the chemokine CCL20, which drives Th17 cells recruitment to the joint.[14]

### Neutrophils

Neutrophils may make up the major fraction of the synovial infiltrate but have remained an infrequent research interest in JIA. sJIA patients have very high levels of the heterodimeric myeloid-related protein (MRP)-8/14, also known as S-100A8/9, secreted by activated monocytes and neutrophils.[74,75] Roth and colleagues have shown that MRP8/14, secreted by cells of the innate immune system, induces autoreactive CD8+ T cells, illustrating how crosstalk between the innate and adaptive immune system can contribute to chronic inflammation.[76]

Examination of neutrophils from JIA has found more than 700 differentially expressed genes between patients and control blood.[77] Genes linked to IL-8 and IFN-γ were prominent among these differences but failed to return to baseline levels after clinical remission. Rather, disease quiescence was associated with an increase in regulatory genes, such as those for TGF-β and retinoic acid, suggesting that remission reflects a balanced state of inflammation and regulation rather than true immunologic resetting.

### Stromal Cells

Resident tissue stromal cells are important targets of both the innate and adaptive immune system and may play an important role in defining the anatomic location of inflammation after systemic immune dysregulation. Synovial fibroblasts from JIA patients secrete metalloproteinases and chemokines in response to locally secreted proinflammatory cytokines[78] and may be an important therapeutic target of the future.

## DISEASE SUBTYPE–SPECIFIC PATHOGENESIS

**KEY POINTS**

**Excessive secretion of IL-1β and IL-6 contributes to many of the clinical features seen in patients with sJIA.**

**The balance between inflammatory and regulatory T cell populations may determine the severity of clinical course in oligoarticular forms of JIA, especially when there is Treg cell dysfunction or instability.**

**RF− polyarthritis shares immunopathologic features with oligoarthritis subtype, whereas RF+ polyarthritis patients are more closely aligned with RA.**

**In ERA, HLA-B27 protein is prone to misfolding, generating an unfolded protein response within cells, which leads to inflammation and arthritis.**

**Psoriasis and psoriatic arthritis have been very strongly linked to pathogenic T cells secreting IL-22 and IL-17.**

### Systemic Juvenile Idiopathic Arthritis

A key role for IL-1β, IL-6, and IL-18, cytokines of the innate immune system, as well as the absence of autoantibodies or a strong association with MHC, have led many to propose sJIA as an autoinflammatory disease. This hypothesis is supported by the close mirroring of these cytokines with the characteristic fever of sJIA, the high levels of IL-6 and IL-18 in serum from active sJIA patients,[79,80] and the enrichment of monocytes in sJIA blood,[81] secreting high levels of IL-1β after activation. Early studies reported a significant higher ratio of IL-1 receptor antagonist (IL-1ra) to IL-1 in these sJIA patients,[79,82] although this may be difficult to interpret because IL-1α and IL-1β are highly labile in serum. Successful treatment with soluble IL-1Ra, anakinra for some patients with sJIA, supports a role for IL-1.[83] Interestingly, IL-1β secretion in sJIA may be mediated by myeloid-related protein (MRP) 8/14 because once this protein is removed from JIA serum, the potential to induce IL-1β is almost completely attenuated.[75] This study confirmed that levels of serum MRP8/14 are very high indeed in active sJIA, and that this measure is both sensitive and specific in distinguishing sJIA from other important diagnoses such as infection or hematopoietic malignancy.

IL-18, a macrophage-derived pro-inflammatory cytokine with a similar signal transduction pathway to IL-1β, is also grossly elevated in sJIA, with serum levels correlating with disease activity. High IL-18 levels may account for the defective NK cytotoxic function found in sJIA.[84] Follow-up studies of anakinra have cast doubt on the primacy of IL-1β in sJIA because more than 50% of patients are either nonresponders or relapse on treatment. Even in responders, it is likely that other inflammatory mediators are involved because treatment response to anakinra fails to correlate with either pre-treatment IL-1β or IL-18 secretion or changes in gene expression of the IL-1β pathway.[85] A specific antibody to IL-1β, canakinumab, is highly effective in sJIA, including in those patients who do not respond to anakinra.[86]

IL-6 is another key player in the pathogenesis of sJIA, secreted by a range of cells, including monocytes. IL-6 levels are elevated in the serum and synovial fluid of sJIA patients, levels correlate with disease activity,[30,79] and clinical features (including growth failure and osteoporosis) can be explained by high levels of IL-6.[87] This evidence led to trials of IL-6 blockade with the monoclonal antibody to soluble IL-6 receptor, tocilizumab. Early trials of tocilizumab demonstrated impressive results in sJIA.[88] A recent multicenter, randomized placebo-controlled, double-blind clinical trial of tocilizumab showed clear efficacy in sJIA (TENDER study).[89]

Gene expression profiling from sJIA patients has confirmed pathways that involve IL-6 and IL-1 and that these can distinguish active from inactive patients.[90] In addition to these roles for monocytes in sJIA, defects of NK cell function, in particular perforin function, are well recognized.[91] The defect in perforin function in active sJIA has

been seen to reverse upon successful treatment with autologous stem cell transplantation.[92]

## Macrophage Activation Syndrome

Macrophage activation syndrome (MAS) is a potentially life-threatening complication of sJIA (as well as sometimes complicating other rheumatologic conditions, such as juvenile systemic lupus erythematosus) thought to result from immune activation of pathogenic T cells and hemophagocytic macrophages.[93] These macrophages express CD163, a scavenger receptor that recognizes haptoglobin-hemoglobin (HP-Hb) complexes. Increased uptake of these complexes within the macrophage leads to production of ferritin, explaining the hyperferritinemia associated with MAS. Soluble forms of CD25, the alpha chain of the IL-2 receptor expressed on T cells, and CD163 are useful biomarkers for MAS in JIA.[94]

MAS shares many similarities with a group of inherited disorders called hemophagocytic lymphocytic histiocytosis (HLH). Defects in the perforin gene and related genes involved in its cytosolic secretory pathway (MUNC13-4, Rab27a, and SH2D1A) have been identified as causes of HLH. When examined in sJIA, polymorphisms in MUNC13-4 and perforin have been associated with MAS in some studies but not others.[95,96] How defects in cytotoxic function lead to MAS is still unclear, but it has been proposed that appropriate clearance of microbial antigens or activated macrophages is prevented, leading to chronic immune stimulation. A gene expression profiling study of active sJIA showed that patients with active sJIA, and in particular those with MAS, have a signature in PBMC that is similar to patients with familial HLH and characteristic of immature erythropoeisis.[97]

## Oligoarthritis

There is increasing evidence that the balance between inflammation and regulation plays a role in driving the clinical phenotype of oligoarthritis patients.[98] The dominance of Treg cells within the joints of patients with persistent oligoarthritis may explain the relatively benign prognosis of this subgroup, in contrast to the extended subgroup who have a low ratio of Treg to Th17 cells. Those who remain in the mild prognosis group have higher numbers of Treg cells in the joint, defined by either CD25 or FOXP3 expression,[14,52] as well as Treg cells that are specific to the human self-antigen HSP60.[54]

Although patients with oligoarthritis JIA are seen with few joints involved, evidence suggests that underlying differences between the groups who remain mild and those who go on to extend are present even very early in disease. Thus genetic differences between persistent and extended oligoarticular phenotypes include variation in the class I MHC allele associations[25] and IL-10.[99] A study of gene expression and cellular and cytokine profiling showed that those children destined to go on to extend had a more heavily IFN-γ–driven and activated macrophage signature in synovial cells, as well as differences in levels of the chemokine regulated on activation, normal T cell expressed and secreted (RANTES) (CCL5), from the start of disease even before extension occurs.[70] Similarly, proteomic profiles are distinct, very early in disease, in those who go on to extended disease.[100] These data have led to the concept of a separate group of patients with oligoarthritis who are destined to progress to more severe disease, the so-called *extended-to-be* group. There is strong evidence to link Th17 cells with autoimmune uveitis, and so agents targeting the IL-17/IL-23 pathway, currently under trial in RA, may ameliorate both joint and eye disease in JIA (typically ANA-positive oligoarticular disease) with uveitis.

## Rheumatoid Factor–Positive Polyarthritis

The presence of RF and a severe erosive disease course suggests that children in this subgroup represent an early presentation of adult-onset RA. Indeed, this subtype of JIA shares genetic associations, in particular at the HLA-DRB1 locus, with adult rheumatoid, in particular, the association with the DRB1*0401 allele at this locus.[25] However, few studies have directly compared immunology between adult and childhood onset of disease. Studies of cyclic citrullinated protein (CCP) positivity in children with JIA have shown association with $RF^+$ polyarticular disease,[101] and there is evidence to support a pathogenic role for RF and autoantibodies against citrullinated peptides by fixation of complement on synovial endothelium. Children with $RF^+$ polyarthritis may share histologic features with adult patients with RA with lymphoid follicles and germinal centers, which may be more abundant than in $RF^-$ patients.[64,102]

## Rheumatoid Factor–Negative Polyarthritis

Patients with $RF^-$ polyarthritis represent a more heterogeneous group than patients with $RF^+$ polyarthritis. Analysis of gene expression data from patients with polyarthritis showed three separate signatures.[71] The first was associated with monocyte-related genes and had the highest proportion of $RF^+$ patients. The third signature found in $RF^-$ patients was associated with reduced $CD8^+$ T cells and increased plasmacytoid DCs. Interestingly, patients did not have overlap between signatures 1 and 3, suggesting distinct immunopathology. It is noteworthy that some patients (24 of 61), who were younger and had a higher rate of ANA positivity, did not fall into a clearly distinct category. A further gene expression study suggested these patients may overlap with $ANA^+$ patients with oligoarthritis, and that age of onset of disease is a more important distinguishing factor than the number of involved joints.[68] As discussed, there are similar immune pathways in $RF^-$ polyarthritis and oligoarthritis patients, and overall disease expression may depend on the balance between immune regulation and inflammation.

## Enthesitis-Related Arthritis

The HLA-B27 allele, recognized many years ago for its association with autoimmune arthritis, appears to play a particular role in pathogenesis through its molecular properties. The presence of a cysteine residue at position 67 of the HLA-B27 alpha1 helix heavy chain makes possible a disulphide bond that promotes the formation of homodimers of the B27 chain.[103] These homodimers, which can

form in absence of antigenic peptide and can induce endoplasmic reticulum stress, are pro-inflammatory and are ligands for NK cell receptors such as KIR3DL1 and KIR3DL2.[104] This abnormal folding of the HLA-B27 molecule, which in the context of microbial antigens drives very high expression of IL-23, may thus promote Th17 cells,[105] which are enriched in ERA synovial fluids.[106] This hypothesis may also explain the association between ERA and inflammatory bowel disease because Th17 cells also drive pathology in the latter condition, and pathogenic cells readily recirculate from gut to joint. Patients with ERA may be particularly prone to disease induction by bacterial pathogens because cells from patients have high expression of pathogen-recognition molecules Toll-like receptor (TLR)2 and TLR4 when compared with healthy controls.[107] It is interesting that ERAP1, which is strongly associated with adult AS and also associated with ERA JIA,[38] is thought to affect the repertoire of peptides available to bind class I MHC by cleavage of N-terminal amino acids from peptide precursors in the ER.[39]

### Psoriatic Arthritis

The etiology of psoriatic arthritis shares features with enthesitis-related arthritis, having genetic association with class I MHC loci, a clonal expansion of CD8 T cells in inflamed joints,[108] and a putative role for Th17 cells. In adult psoriasis and psoriatic arthritis, there is strong evidence that Th17 cytokines, IL-22, and IL-17 contribute to the disease process (see Chapter 77). The receptor for IL-23, a key cytokine that induces Th17 cells, is linked to the juvenile form of the disease, and IL-23 blockade appears promising in trials of skin and joint disease in adult patients.[109] Evidence of genetic associations with autoinflammatory genes in juvenile patients with psoriatic arthritis suggests that the innate immune system may also play a role.[110]

## CONCLUSION

The heterogeneity of childhood arthritis is complex but is gradually being characterized and harnessed through the application of novel methods, including gene expression profiling, proteomics, and high-throughput genetics and the major progress in our understanding of the immunologic processes involved. In this chapter, cellular processes at play in JIA have been considered individually; the immune system acts in concert to create vastly complex networks. The challenge is to understand the functional hierarchy of these networks and discover checkpoints that will be amenable to therapeutic targeting in the future.

As well as new treatments, better biomarkers are required for use in the clinic. The task in coming years will be to integrate the vast body of data that will be generated through these novel approaches to allow the development of more precise classification definitions, and perhaps more important, predictive tools with which to drive treatment choices for patients.

CHAPTER 107

# Clinical Features and Treatment of Juvenile Idiopathic Arthritis

Joyce J. Hsu • Tzielan C. Lee • Christy I. Sandborg

**KEY POINTS**

- Juvenile idiopathic arthritis (JIA) is the umbrella term for a family of heterogeneous childhood arthritides of unknown cause.
- JIA affects at least 1 in 1000 children. The goals of treatment in JIA are complete suppression of inflammation on medications and remission when possible.
- Oligoarticular JIA, characterized by early age of onset, female predominance, anti-nuclear antibody positivity, and subacute anterior uveitis, occurs only in childhood.
- Systemic JIA is distinct from other subgroups of JIA in its equal sex distribution, lack of autoantibodies and human leukocyte antigen associations, and increased responsiveness to IL-1 and IL-6 inhibition compared with TNF inhibition.
- Juvenile spondyloarthritis typically occurs in children older than 6 years, but sacroiliitis may not develop until adolescence.
- Because bone erosions on conventional radiographs are late radiographic findings in growing children, detection of early joint damage may require different imaging modalities.
- Considerable progress in understanding the genetics and pathogenesis of JIA has revealed subtype-specific associations as well as some common mechanisms of disease that will translate to more effective and targeted therapies.

Juvenile idiopathic arthritis (JIA) is the most common rheumatic disease in childhood, but actual estimates of prevalence and incidence vary remarkably in different geographic regions, ranging from 7 to 400 per 100,000 children, reflecting variations in disease reporting, classification, and racial/ethnic and environmental differences in disease expression.[1] Reasonable working estimates are 150 per 100,000 children, making JIA one of the most common chronic diseases of childhood. There are significant differences in the disease manifestations in children compared with adults, with some types occurring exclusively in children. This chapter discusses the current understanding of the key clinical and diagnostic features of the various forms of JIA, treatment approaches, and outcomes. The rapid growth in understanding the biologic basis for JIA and the ongoing development of targeted therapies for rheumatic diseases are likely to lead to enhancements in these recommendations. Data concerning long-term disease course and outcome in children with JIA in this modern treatment era remain limited, and there are international prospective inception cohorts of children with arthritis designed to address these gaps in knowledge.[2,3]

## CLASSIFICATION CRITERIA FOR JUVENILE IDIOPATHIC ARTHRITIS AND DIFFERENTIAL DIAGNOSIS

In the past, different groups used various nomenclature to classify children with persistent arthritis, including "juvenile rheumatoid arthritis" (American College of Rheumatology [ACR]) and "juvenile chronic arthritis" (European League against Rheumatism), which created problems in comparing research studies and outcomes. The goal of the International League of Associations for Rheumatology (ILAR) is to identify subtypes of JIA for research purposes that are homogeneous and mutually exclusive. JIA classification is currently based on predominant clinical and laboratory features and the number of involved joints at disease onset,[4] which are presented in Table 107-1. However, classification systems are ever changing, and categorization may evolve to more biologically and genetically similar subgrouping, especially with recent advances in etiology and pathogenesis.[5,6]

The patterns in children with rheumatic diseases can overlap with other concerning diagnoses, such as malignancies, infection, and trauma (especially nonaccidental). Therefore it is crucial to evaluate these diagnostic possibilities before accepting the diagnosis of JIA. The ILAR categories are meant to simplify classification and are useful for typical presentations of disease. However, if a patient does not easily fit into the ILAR classification system, clinicians must carefully consider all other possibilities, rheumatologic and nonrheumatologic. For example, among patients with acute lymphocytic leukemia (ALL), 15% to 30% are seen with musculoskeletal symptoms without blasts in the peripheral smear and may be misdiagnosed with JIA. In addition, anti-nuclear antibody (ANA) status, rash, radiographic abnormalities, and objective signs of arthritis were found to not be helpful in distinguishing between ALL and JIA.[7]

## OLIGOARTICULAR JUVENILE IDIOPATHIC ARTHRITIS

Oligoarticular JIA accounts for as many as 20% of all new rheumatic diagnoses in the general pediatric rheumatology clinic[8] and is the most prevalent of all the JIA subcategories, comprising 30% to 60% of all patients with JIA in

**TABLE 107-1** ILAR Classification Criteria for Juvenile Idiopathic Arthritis (JIA)

**General Definition of JIA**

Juvenile idiopathic arthritis is arthritis of unknown etiology that begins before the sixteenth birthday and persists for at least 6 weeks; other known conditions are excluded.

| Subcategory | Definition | Exclusions |
|---|---|---|
| **Oligoarticular JIA**<br>Two subcategories are recognized:<br>1. Persistent oligoarticular JIA: affecting ≤4 joints throughout the disease course<br>2. Extended oligoarticular JIA : affecting a total of >4 joints after the first 6 months of disease | Arthritis affecting 1-4 joints during the first 6 months of disease | a. Psoriasis or a history of psoriasis in the patient or a first-degree relative<br>b. Arthritis in a human leukocyte antigen (HLA)-B27$^+$ male beginning after the sixth birthday<br>c. Ankylosing spondylitis, ERA, sacroiliitis with inflammatory bowel disease, Reiter's syndrome, or acute anterior uveitis, or a history of one of these disorders in a first-degree relative.<br>d. The presence of IgM RF on at least 2 occasions, at least 3 months apart<br>e. The presence of systemic JIA in the patient |
| RF$^-$ polyarticular JIA | 1. Arthritis affecting ≥5 joints during the first 6 months of disease, **and**<br>2. Test for RF is negative | a, b, c, d, e |
| RF$^+$ polyarticular JIA | 1. Arthritis affecting ≥5 joints during the first 6 months of disease, **and**<br>2. ≥2 positive RF tests (as routinely defined in an accredited laboratory), at least 3 months apart during the first 6 months of disease | a, b, c, e |
| Psoriatic arthritis | 1. Arthritis and psoriasis, **or**<br>2. Arthritis and at least 2 of the following:<br>a. Dactylitis<br>b. Nail pitting (minimum of 2 pits on ≥1 nails at any time) or onycholysis<br>c. Psoriasis in a first-degree relative | b, c, d, e |
| Enthesitis-related arthritis | 1. Arthritis *and* enthesitis, **or**<br>2. Arthritis *or* enthesitis, with at least 2 of the following:<br>a. The presence of or a history of sacroiliac joint tenderness and/or inflammatory lumbosacral pain<br>b. The presence of HLA-B27<br>c. Onset of arthritis in a male >6 years of age<br>d. Acute (symptomatic) anterior uveitis<br>e. History of ankylosing spondylitis, ERA, sacroiliitis with inflammatory bowel disease, Reiter's syndrome, or acute anterior uveitis in a first-degree relative | a, d, e |
| Systemic JIA | Arthritis in ≥1 joints with, or preceded by, fever of at least 2 weeks' duration that is documented to be daily and quotidian (fever that rises to ≥39° C once a day and returns to ≤37° C between fever peaks) for at least 3 days, and accompanied by ≥1 of the following:<br>a. Evanescent (nonfixed) erythematous rash<br>b. Generalized lymph node enlargement<br>c. Hepatomegaly and/or splenomegaly<br>d. Serositis | a, b, c, d |
| Undifferentiated arthritis | Arthritis that fulfills criteria in no category or in ≥2 of the above categories | |

ERA, Enthesitis-related arthritis; ILAR, International League of Associations for Rheumatology; RF, rheumatoid factor.

From Petty RE, Southwood TR, Manners P, et al: International League of Associations for Rheumatology classification of juvenile idiopathic arthritis: second revision, Edmonton, 2001. *J Rheumatol* 31(2):390–392, 2004.

North America and Europe.[9] Oligoarticular JIA has no adult equivalent. The peak age of onset occurs in Caucasian children ages 2 to 4 years from the United States and Europe, and the female to male ratio is 3:1.[10] It is rare in African-Americans,[11] Native Americans,[12] and southern Asians. Two general subgroups are recognized within oligoarticular JIA: first, persistent oligoarticular JIA, in which the number of joints affected by arthritis remains less than five throughout the disease course; second, extended oligoarticular JIA, in which arthritis develops in additional joints 6 months after disease onset. Extension occurs in 30% to 50% at 4 to 6 years after onset of disease.[13-15] Symmetric disease, ankle and/or wrist involvement, and an elevated erythrocyte sedimentation rate

(ESR) in the first 6 months of disease might be associated with extension.[13,15,16]

Oligoarticular JIA usually manifests as an asymmetric arthritis affecting one or two large joints, especially of the lower extremities, with the knee the most commonly affected, followed by the ankle, wrist, and digits. Involvement of the hip and back, especially in young children, is so unusual that extensive evaluation is warranted to rule out other conditions such as infection or malignancy. Significant constitutional and systemic symptoms are unusual in oligoarticular JIA and, if present, should raise concern regarding the accuracy of the initial diagnosis. Pain in an obviously inflamed joint is surprisingly minimal compared with septic arthritis, and in as many as 25% of cases, the symptoms may be subtle with parents only noticing a limp and joint swelling. In a young child, there is reluctance to walk and bear weight with a return to crawling after a period of immobility, such as in the morning or after a nap. There is a high risk for a relatively asymptomatic chronic uveitis, especially in $ANA^+$ individuals, requiring regular ophthalmology examinations to detect early changes (see Uveitis).

Among children with oligoarticular JIA, a positive ANA in low to moderate titers (1:40 to 1:320) is seen in 70% to 80% of children with persistent oligoarticular JIA and 80% to 95% with extended oligoarticular JIA.[10] The rate of ANA positivity is even higher in girls with early onset disease.[17] The typical child with oligoarticular JIA will have normal white blood counts, normal or mild-moderately elevated acute phase reactants, and, in some cases, mild anemia.

The differential diagnosis of oligoarticular JIA includes other JIA subtypes, especially juvenile spondyloarthritis (JSpA) and juvenile psoriatic arthritis (JPsA); other rheumatic diseases of childhood, or other inflammatory conditions such as inflammatory bowel disease (IBD). Nonrheumatic causes of joint pain and swelling should also be ruled out, such as septic arthritis, benign or malignant tumors, reactive arthritis, foreign body synovitis, pigmented villonodular synovitis, arterial-venous malformation, bleeding disorders (such as hemophilia), or bony fractures, including nonaccidental injury. Mild trauma is rarely a cause of joint swelling in young children because serious sprains or orthopedic problems such as meniscal tears or ligamentous injury are exceedingly rare. In general, ligaments and tendons are stronger than growing bone in children, and the bone-ligament or bone-tendon junction is the weakest link. Therefore fractures are more common in children than adults. Transient joint effusions can develop in children with hypermobility after exercise.[18] Lyme disease (in an endemic area) can cause recurrent monoarticular arthritis (typically involving the knee and often with popliteal cysts), usually for less than 6 weeks.

## RHEUMATOID FACTOR–NEGATIVE POLYARTICULAR JUVENILE IDIOPATHIC ARTHRITIS

Rheumatoid factor $(RF)^-$ polyarticular JIA makes up 10% to 30% of all JIA cases, with a bimodal distribution of age of onset, with the first peak at 1 to 4 years of age and the second peak at 10 to 12 years. Girls are more commonly affected than boys, with a ratio of 3.2:1, and subacute anterior uveitis occurs in 4% to 25% of cases.[10] Polyarticular JIA is the most common JIA subtype in African-Americans and Native Americans, who often have the most severe disease with the worst prognosis.[11,12] Patients with $RF^-$ polyarticular JIA have more involvement of hip, shoulder, cervical spine, and distal interphalangeal joints than in adults. Some authors distinguish between two clinical subgroups based on ANA status: (1) an $ANA^+$ form that resembles oligoarticular JIA, consisting of young girls aged 6 years or less, with an asymmetric arthritis in more than four joints and high risk of uveitis, and (2) an $ANA^-$ form that is similar to adult-onset $RF^-$ rheumatoid arthritis (RA), characterized by older patients, symmetric synovitis of large and small joints, a greater cumulative number of affected joints, and less uveitis. The similarities between $ANA^+$, $RF^-$ polyarticular JIA and oligoarticular JIA have led to the hypothesis that these two entities are actually in the same disease spectrum.[6] $RF^-$ polyarticular JIA may be associated with low-grade fevers, fatigue, poor growth, weight loss, elevated acute phase reactants, mild anemia, and ANA positivity in as many as 40% of patients. Even though RF is negative, 50% to 80% of patients are anti-citrullinated protein antibody $(ACPA)^+$,[10] using high-sensitivity but low-specificity testing methods.[19]

The differential diagnosis of $RF^-$ polyarticular JIA includes the other JIA subtypes, such as JSpA which should be considered particularly in boys older than 6 years because sacroiliac (SI) involvement may not occur until adolescence. Other major considerations include other rheumatic conditions; malignancies such as lymphoma and leukemia; and infections such as *Neisseria gonorrhoeae*, rubella, parvovirus, and Lyme disease.

## RHEUMATOID FACTOR–POSITIVE POLYARTICULAR JUVENILE IDIOPATHIC ARTHRITIS

$RF^+$ polyarticular JIA is a well-characterized JIA subcategory and is part of the same disease spectrum as adult $RF^+$ RA,[20] sharing immunogenetic and serologic factors. This subcategory makes up 5% to 10% of cases of JIA[10] with reported female-to-male ratios between 5.7-12.8:1.0.[8,21] Age of onset occurs in late childhood or adolescence, about ages 10 to 13 years, and typically is an aggressive, symmetric polyarthritis affecting many small and large joints. Hip involvement is common and may be debilitating. The arthritis can be quite severe, often resulting in bony erosions and joint destruction. Radiologic changes tend to take place early,[22] especially in hands and feet. With active disease, patients may have mild systemic signs and symptoms. Rheumatoid nodules occur in as many as 10% of cases, most frequently around the elbow. Other extra-articular manifestations are reported less often than in adults. Uveitis is unusual, seen in less than 2% of patients.[10]

Polyarticular JIA may be associated with mild to moderate inflammation, such as elevated acute phase reactants and a normocytic, normochromic anemia. By definition, all patients have immunoglobulin (Ig)M–anti-IgG RF. The ANA test is positive in approximately 55% of patients,[10] and ACPAs have been reported in 57% to 73%.[23,24] The prevalence of ACPAs varies in polyarticular JIA but usually coincides with RF status.[25]

## JUVENILE SPONDYLOARTHRITIS/ ENTHESITIS-RELATED ARTHRITIS

The current classification criteria for JSpA has been split into two forms: undifferentiated and differentiated. The undifferentiated form is made up of seronegative enthesopathy and arthropathy syndrome (SEA) and enthesitis-related arthritis (ERA; JIA subtype in the ILAR classification), whereas the differentiated form includes juvenile ankylosing spondylitis (AS), psoriatic arthritis, reactive arthritis, and arthritis associated with IBD. Unfortunately, the clinical features vary from adult spondyloarthritis, making adult classification criteria inaccurate for this pediatric group. Because of the significant heterogeneity of this disease phenotype, it has been difficult to propose classification criteria.[26] JSpA accounts for approximately 20% of JIA, with onset usually after age 6 years and higher prevalence in boys (male : female ratio 7 : 1), although girls may be underrecognized because of milder disease and less axial involvement.[27] In many cases, JSpA is diagnosed initially as oligoarticular JIA.[8] These patients rarely have sacroiliitis until adolescence, and instead usually are seen with lower-limb arthritis and enthesitis.[4] The articular manifestations of JSpA include hip and peripheral arthritis with an asymmetric oligoarthritis most commonly in the lower limb. As many as one-third of JSpA children will have the classic finding of tarsitis, which is inflammation of the subtalar joint and the surrounding tendon sheaths. Approximately 25% of JSpA patients have polyarthritis presentation at onset.[26]

Enthesitis (inflammation of the tendon insertion site) is seen in 60% to 80% of JSpA patients. It is an early manifestation and occurs more frequently in children than in adult-onset AS.[28] The most frequent locations include the inferior pole of the patella (50%); plantar fascial insertion into the calcaneus (38%) or metatarsal head (22%); and Achilles tendon insertion site into the calcaneus (22%).[29] In addition, enthesitis may be seen at the 2 o'clock and 10 o'clock positions on the patella, greater trochanter, tibial tuberosity, and the base of the fifth metatarsal. Children may also report vague buttock pain, groin pain, or heel pain. At onset, spinal symptoms are rare, but a subgroup of children with ERA will progress to features more typical of adult AS, with SI joint and spinal inflammation during adolescence. This progression is more likely in boys who are human leukocyte antigen (HLA)-B27$^+$ and have spinal or SI pain within 1 year of diagnosis.[30] The modified Schober's test can be used to evaluate lower lumbar flexibility, with a change less than 6 cm considered abnormal.[31] Because thoracic excursion varies greatly in a growing child, only sequential measurements are helpful. In the adolescent, any thoracic excursion less than 5 cm should be regarded as abnormal.[28]

JSpA is associated with an acute anterior uveitis in 6% to 27% of children, which typically presents as an acutely red, painful, and photophobic eye that needs immediate medical attention because, if left untreated, it may lead to blindness.[28,32,33] It is more common in HLA-B27$^+$ boys. Cardiovascular disease, although uncommon, can be severe in patients with juvenile AS, with inflammatory aortic regurgitation reported in as many as 10% of patients.[34] Subclinical gut inflammation has been known to be associated with JSpA, with findings of as many as two-thirds of patients observed to have changes similar to patients with Crohn's disease.[35] Arthritis associated with IBD is also seen in children with two distinct patterns of joint involvement: (1) peripheral arthritis more common than (2) sacroiliitis and spondylitis. Additional clinical manifestations unique to arthritis associated with IBD include clubbing, periostitis, erythema nodosum, pyoderma gangrenosum, osteoporosis, and rarely, hypertrophic osteoarthropathy. The peripheral arthritis activity correlates with gut disease activity, unlike the SI joint activity, which tends not to correlate.[31]

Reactive arthritis is categorized under JSpA, following infection with organisms from the gastrointestinal tract (i.e., *Salmonella*, *Shigella*, *Yersinia*, *Campylobacter*, *Clostridium difficile*) or genitourinary tract (i.e., *Chlamydia* or *Ureaplasma*) without actual infection in the joint tissues. Usually self-limited, the arthritis can persist and transform into a more chronic arthropathy.[36] In addition to the arthritis, urethritis and uveitis have been documented in children to complete the classic triad for reactive arthritis. The clinical infection usually precedes the arthritis, enthesitis, or extra-articular disease by 1 to 4 weeks.

Compared with adults, in whom radiologic evidence of sacroiliitis is the diagnostic hallmark of AS, radiologic evaluation in children with JSpA is less often diagnostic because sacroiliitis is rare as a presenting symptom. Interestingly, the presence of hip disease in a patient with JSpA increased the likelihood of future sacroiliitis 11-fold, whereas the presence of dactylitis decreased it.[37] MRI with contrast is increasingly used to detect evidence of acute sacroiliitis without chronic changes in children. MRI has also been used to evaluate enthesitis.[38]

HLA-B27 is present in 60% to 80% of patients with JSpA, depending on ethnicity.[26] The ESR may be mildly or markedly raised, and there may be a mild anemia, but these should also raise the suspicion that the child may have subclinical IBD. RF is negative, and ANA may be positive.

The differential diagnosis of JSpA includes true infectious or postinfectious arthritides (viral, rheumatic fever, post-streptococcal, Lyme). More benign entities such as toxic synovitis and benign limb pains of childhood (growing pains), as well as more concerning entities such as malignancies and solid tumors, should also be considered. Orthopedic diagnoses, such as Legg-Calvé-Perthes disease, slipped capital femoral epiphyses disease, and Osgood-Schlatter disease, and less common rheumatologic diseases, such as SAPHO (synovitis, acne, pustulosis, hyperostosis, and osteomyelitis), Kawasaki's disease, and vasculitis, can share similar articular and extra-articular manifestations with JSpA. Both Behçet's disease and familial Mediterranean fever can have sacroiliitis features and therefore could be mistaken for JSpA.[39] Last, children with widespread amplified musculoskeletal pain may have very tender entheses that can be mistaken for enthesitis.

## JUVENILE PSORIATIC ARTHRITIS

Juvenile psoriatic arthritis (JPsA) was initially defined as juvenile-onset arthritis associated with psoriasis occurring at some point during the disease course. This definition has been further expanded to arthritis in the presence of

psoriasis or at least two minor criteria—nail pits/onycholysis, dactylitis, or a first-degree family history of psoriasis—in the absence of specific exclusions.[4,39,40] JPsA represents 2% to 5% of all JIA, with a slight female preponderance and a bimodal pattern of onset (2 to 4 years and 10 to 12 years).[35,39,41,42] There are noted differences between the two onset groups, with the younger-onset cohort more likely to be ANA$^+$, female, and have chronic uveitis, and the older-onset cohort more likely to have HLA-B27 positivity, enthesitis, and axial disease.[35]

The psoriasis typically occurs within 2 years of the onset of arthritis, and for the majority of children, the skin symptoms follow the arthritis symptoms.[28] As many as 80% of children have a classic psoriatic vulgaris or plaque psoriasis characterized by well-demarcated, erythematous, scaly lesions occurring over extensor surfaces (elbows and knees), scalp, and trunk.[28,43,44] However, in small children younger than 2 years, the most common finding is psoriatic diaper rash.[44] Additional areas that should be evaluated include the hairline behind the ears, the navel, the groin region, and superior to the gluteal cleft.[28]

Because JPsA shares similar manifestations with multiple subtypes of juvenile arthritis, there is not one specific articular presentation. Patterns of joint involvement can be oligoarthritis or polyarthritis, with 55% to 70% of patients with JPsA having an oligoarthritis onset (<5 joints), although evolution to polyarthritis can occur in as many as 52%.[45,46] In one study, as many as one-third of patients were diagnosed with another JIA subtype before the diagnosis of JPsA after a mean of 4.2 years.[45] There were no differences in ANA status, HLA-B27 positivity, or uveitis frequency between oligoarticular JIA versus JPsA patients with fewer than 5 joints involved at onset. However, JPsA patients with fewer than 5 joints involved at onset did have more dactylitis, more small joint involvement, and less large joint involvement than oligoarticular JIA patients.[39,47-49] Children with psoriatic arthritis may have mild elevated acute phase reactants and mild anemia of chronic disease. However, as many as one-third have no laboratory evidence of inflammation.

## SYSTEMIC JUVENILE IDIOPATHIC ARTHRITIS

Systemic JIA (sJIA), which makes up 10% of all JIA, has unique characteristics that include fever, specific rash, and significantly elevated inflammatory markers in addition to arthritis. Recent research has identified biologic differences between sJIA and the other JIA subcategories, including prominent involvement of components of the innate immune system (in particular, inflammatory cytokines IL-1, IL-6, and IL-18; neutrophils; and monocytes/macrophages), suggesting that sJIA may be in the autoinflammatory disease spectrum.[50]

sJIA occurs at any age, with a tendency toward patients younger than 5 years, peaking around 2 years of age.[51,52] Rarely, it occurs in adults and is called *adult-onset Still's disease*. The gender predilection has stayed neutral. The systemic features of this disease are striking and are always present at onset, often predominating the clinical presentation. The arthritis may not be clinically present at onset, although arthralgias and myalgias are almost universally present at onset.[28] The fever is typically spiking in character with a peak of at least 39° C daily, occurring once or twice a day. Interestingly, the temperatures can be subnormal between fevers. The child appears unwell and irritable during the fever but often recovers when afebrile. In 80% of patients, the fevers are accompanied by an evanescent, migratory, salmon pink, and sometimes urticarial macular rash (Figure 107-1).[51] The rash typically spares the face and can occur without specific pattern on any part of the trunk or extremities. It can be subtle and scattered or diffuse and almost confluent. A helpful diagnostic feature is that the rash can be elicited by the Koebner phenomenon.

**Figure 107-1** Typical rash of systemic juvenile idiopathic arthritis, with small 1 to 5 mm flat or slightly raised salmon pink macules.

Other systemic features include lymphadenopathy, hepatosplenomegaly, serositis (pleural/pericardial involvement/abdominal pain), headaches, and sore throat. Pericarditis and pericardial effusions are the most common organ system manifestations, occurring in as many as 10% of patients.[51] A serious life-threatening systemic manifestation called *macrophage activation syndrome* (MAS) is discussed in more detail later. The arthritis in sJIA can vary from minimal to oligoarthritis to polyarthritis presentation[51] and typically does not correlate with the severity of the systemic manifestations.[53] Tenosynovitis and synovial cyst formation can also be seen. Although the systemic manifestations can be serious initially, the long-term morbidity is the result of severe articular damage and adverse effects of medications, especially chronic corticosteroids.

There are no diagnostic tests for sJIA, but there are characteristic patterns of laboratory abnormalities, including high inflammatory markers, significant leukocytosis with neutrophilia and bandemia, thrombocytosis, and anemia. Liver transaminases, aldolase, ferritin, fibrin split products, and coagulation screen may be abnormal in severe cases and can be signs of early or impending MAS. ANA or other autoantibodies are rarely present. Inflammatory cytokine gene expression profiles distinguish sJIA from other febrile inflammatory diseases seen in children, correlate with response to IL-1 inhibitor therapy, and may lead to more specific tests in the future.[54,55]

Because of the nonspecific nature of the characteristics of sJIA, the diagnosis can be difficult and should be approached as a diagnosis of exclusion. Infections, Kawasaki's syndrome, malignancy, and other autoimmune diseases can have similar symptoms; therefore it is necessary to

screen for infectious agents and malignancies, especially leukemia and neuroblastoma, with appropriate tests including cultures, bone marrow aspiration and biopsy, and urinary vanillylmandelic acids. The recurrent fever syndromes are often mistaken for sJIA, but the character of the fevers and the fixed rashes associated with these syndromes should alert the clinician to a different diagnosis.

### Special Considerations: Macrophage Activation Syndrome

Overt life-threatening MAS will develop in approximately 10% of patients with sJIA, and a milder form will develop in as many as 30%. If inadequately treated, the milder form could lead to full-blown MAS.[54,56] MAS is a form of secondary or acquired hemophagocytic lymphohistiocytosis (HLH) seen with rheumatic disease.[57] The mortality rate can be 20% to 30%, accounting for the majority of the mortality seen in all patients with JIA.[58] The main manifestations include unrelenting high fevers, hepatosplenomegaly, lymphadenopathy, severe cytopenias, liver dysfunction, central nervous system (CNS) involvement (seizures/coma), and coagulopathy. Ferritin often exceeds 10,000 ng/mL, and coagulopathy can be impressive, with elevated prothrombin and partial thrombin times, hypofibrinogenemia, petechiae, mucosal bleeding, epistaxis, and hematemesis. Often MAS is heralded by decreased leukocyte and platelet counts, falling ESR, liver dysfunction, hyperferritinemia and elevated D-dimers.[56] Histologically, most patients with MAS show expansion of well-differentiated macrophages, exhibiting hemophagocytosis in the bone marrow, lymph nodes, and other organs such as the liver and lungs. There is no gender, age, or race predilection for MAS in sJIA. Half of MAS cases studied were associated with active disease, one-third with infectious triggers (Epstein-Barr virus, varicella, coxsackie, parvovirus B19, hepatitis A, *Salmonella*, and *Pneumocystis*), 4% with medication exposures (aspirin, NSAIDs, sulfasalazine [SSZ], methotrexate [MTX], etanercept, anakinra, and gold salts), and the rest unidentified.[56] Because many patients who are receiving these medications have active disease, it is challenging to attribute MAS to disease activity versus medications.[59,60] Current understanding of pathophysiology includes excessive inflammatory cytokines, activation of T cells and macrophages, poor natural killer and CD8 cell cytolytic activity, and low levels of perforin expression.[54,61] Soluble IL-2Rα receptors and soluble CD163 are increased several-fold in MAS.[62,63] Recently, *MEFV* mutations seen in Familial Mediterranean fever have been identified in 18.5% of patients with sJIA, and these patients were noted to have the most resistant disease.[64]

## TREATMENT

With the current development of increasingly more effective biologic treatment for arthritis, pediatric rheumatologists now aim to achieve complete disease remission. Several studies support the paradigm of treating aggressively to reach inactive disease as early as possible in the disease course, which may ultimately lead to better outcome, such as improved quality of life, shorter periods of time spent in active disease, and less long-term joint damage.[65] Based on ACR published guidelines for treatment of JIA,[66,67] a comprehensive picture of each patient's clinical features, JIA subtype, disease activity, and prognostic factors should drive treatment escalation. Comparative effectiveness studies based on consensus treatment plans developed by rigorous consensus methodology, are currently underway for systemic and polyarticular JIA.[68-70] Integration of these published ACR guidelines, the consensus treatment plans, and randomized control trials (RCT) have been used to inform the treatment recommendations in this chapter. There are now validated definitions of core sets, disease activity, clinical inactive disease (CID), disease severity, improvement, and remission that can be used in individual practice and research trials to determine treatment changes.[71,72] The following paragraphs summarize general information about different therapies used in children, followed by specific treatment approaches for the different subtypes of JIA. Table 107-2 shows medications, dosing, route, and safety monitoring recommendations.

### Nonsteroidal Anti-inflammatory Drug Use in Children

NSAIDs may help control symptoms of pain and stiffness, but do not alter the natural history of JIA. NSAIDs are frequently used for symptom control as an adjunctive therapy to more definitive therapies. The overall use of NSAIDs is declining in the era of biologic treatment.[73] In general, NSAIDS should only be considered as monotherapy in initial therapy in patients with low disease activity. If control is not achieved in 1 to 2 months, additional therapy should be considered.[66]

**TABLE 107-2** Commonly Used Medications in Juvenile Idiopathic Arthritis[66,67,234-236]

| Medication | Typical Dose and Administration Route | Typical Frequency |
|---|---|---|
| Abatacept<br>*FDA approved for poly JIA ages >6 years | 10 mg/kg (max 1000 mg) IV | Load at 0, 2, 4 wk, then every 4 wk |
| Adalimumab<br>*FDA approved for poly JIA ages ≥2 years | 24 mg/m$^2$ SQ<br><30 kg: 20 mg SQ<br>≥30 kg: 40 mg SQ | Every 2 wk (arthritis)<br>Every wk (uveitis) |

## Intra-articular Steroid Injections

The use of intra-articular triamcinolone hexacetonide (THA), 1 mg/kg in large joints, such as the knee, and 0.5 mg/kg in smaller joints, such as the ankle, has been found to be superior to triamcinolone acetonide (TA),[74] betamethasone, and methylprednisolone acetate in RCTs.[75-80] Early treatment is associated with better outcome,[81] and intra-articular steroids (IAS) are expected to result in clinical improvement of arthritis for as long as 4 months. Therefore, if arthritis recurs, joint injections can be repeated as many as three times in a 12-month period. Difficult-to-reach joints, such as the hip, SI joint, temporomandibular joint (TMJ), and subtalar joint, may be injected by using ultrasound or fluoroscopy. Multiple IAS injections in the knee, ankle, or wrist do not appear to change the mean cartilage thickness.[82] IAS should be administered under sedation or general anesthesia for the young. The use of IAS for active arthritis has been recommended by the ACR guidelines, regardless of concurrent therapy, JIA subtype, disease activity, prognostic features, or joint contracture. If the duration of clinical improvement is shorter than 4 months, systemic treatment (e.g., MTX) may be indicated.[66]

## Corticosteroid Use in Children with Juvenile Idiopathic Arthritis

In general, systemic corticosteroids should be used sparingly in the treatment of any subgroup of JIA because of the severe morbidity associated with chronic use, even at low doses. Newer therapeutic modalities such as biologics may eliminate the need for any corticosteroids or limit the doses needed. The evidence for use of corticosteroids for the synovitis of JIA is controversial and conflicting, and the ACR was unable to make any specific recommendations for JIA treatment regarding corticosteroid use, except in sJIA for severe systemic features.[66] However, in some cases, low doses of corticosteroids (0.1-0.5 mg prednisone equivalent/kg/day) or brief high-dose regimens (intravenous [IV] methylprednisolone 30 mg/kg/day, maximum dose 1000 mg daily for 1 to 3 days) may be used in polyarticular JIA to bridge constitutional features of pain and fatigue while waiting for disease-modifying anti-rheumatic drugs (DMARDs) or biologic therapies to reach therapeutic effect.

## Methotrexate

MTX is effective, safe, and the most commonly used DMARD in JIA.[83,84] In a retrospective cohort study involving all JIA subtypes, the strongest predictor of response to MTX at 6 months of treatment was the time from diagnosis to start of MTX, suggesting that starting MTX early will lead to a better response.[85] The ACR guidelines support a maximum dose of 0.6 mg/kg once weekly (equivalent to 15 mg/m$^2$/wk, maximum 25 mg/week) of parenteral MTX.[66] In patients with lower disease severity, lower doses (8-12.5 mg/m$^2$/wk, oral or parenteral) may be effective, and these doses are similar in safety.[86] Most pediatric rheumatologists start folic acid at 1 mg/day, but daily folate supplementation remains controversial. Liver biopsies are not indicated except in unusual circumstances. Some children develop an intolerance to MTX, and leflunomide may be used as an alternative.[87,88] Both MTX and leflunomide are associated with teratogenic effects.

## Biologic Agents

### Tumor Necrosis Factor Inhibitors

TNF inhibitor agents are effective in many children with polyarthritis of any JIA subtype, although less in sJIA.[89] In RCTs, etanercept and adalimumab have high efficacy and safety in patients with JIA with polyarthritis.[90,91-96,97,98] Combination MTX with etanercept or adalimumab seems to be more effective than TNF monotherapy.[91,97]

Infliximab did not reach statistical significance for efficacy in an RCT in polyarticular-course JIA patients[99]; however, there was a trend for a higher dose 6 mg/kg/infusion to be more effective than the adult dose of 3 mg/kg/infusion. Higher doses of infliximab can be given[100] if loss of efficacy with time occurs, possibly from the formation of anti-infliximab antibodies. Low-dose MTX given concomitantly may reduce the risk of neutralizing antibody development, as it does in adults.

In August 2009, the U.S. Food and Drug Administration issued a black box warning on the increased risk of cancer, particularly lymphoma, in children and adolescents receiving TNF inhibitors for arthritis or IBD.[101] The other adverse events involved with TNF inhibitors are similar to that of adults and have been reported in children as well, including serious infections, demyelinating processes, optic neuritis, injection-site reactions or infusion reactions, and development of autoimmune conditions. A recent cohort study showed that patients with JIA who were not taking MTX or TNF inhibitors still had a twofold increased rate of serious bacterial infections requiring hospitalization. Children with JIA did not have an increased rate of infection with MTX or TNF inhibitor use but had three times more infections with high-dose steroid use (≥10 mg/day of prednisone or equivalent).[102] In most, but not all, of the recent epidemiologic studies to approximate malignancy risk, children with JIA appeared to have a twofold to fourfold increased risk of malignancy compared with children without JIA, which did not appear to be significantly associated with treatment, including TNF inhibitors.[103,104] Efforts are underway in the United States and Europe to capture post-marketing serious adverse events (SAE) with all biologics using disease registries or within the context of an established multicenter research network.[105,106]

### Abatacept

Abatacept, a fusion protein of the naturally occurring co-stimulatory inhibitory molecule cytotoxic T lymphocyte–associated protein 4 and the Fc portion of IgG, is currently the only T cell co-stimulatory inhibitor used in inflammatory arthritis. It is safe and efficacious in a RCT of polyarticular-course JIA patients who had inadequate response or intolerance to DMARD or TNF inhibitor in the past.[107] Abatacept continued to be clinically significant with durable effectiveness in the 3-year open-label extension study. Some patients require longer periods for optimal response (>3 to 4 months) compared with TNF inhibitors.[108]

### IL-1 Inhibitors

Anakinra was the first IL-1 inhibitor developed from the endogenous IL-1 receptor antagonist (IL-1Ra). Although anakinra has not been approved for use in JIA, a series of studies suggested that anakinra was effective in sJIA,[109-111] leading to extensive use in this difficult-to-treat disease subtype. Two additional IL-1 inhibitors, canakinumab and rilonacept, have been developed and are highly effective and safe in RCTs of patients with sJIA.[112-114] Canakinumab is a fully human monoclonal antibody against IL-1B that can be administered monthly. Rilonacept is a fusion protein of the IL-1 receptor molecules and the Fc portion of IgG that can bind to IL-1α, IL-1B, and IL-1Ra, and is given every 2 weeks. The safety profile of IL-1 inhibitors is less understood compared with other agents because of the small numbers of patients in the phase III trials and the overall smaller numbers of patients with sJIA. In addition, patients with sJIA can have severe disease complications, making it difficult to attribute SAEs to a specific treatment versus underlying disease. Tuberculosis, opportunistic infection, demyelinating disease, or malignancy have not been noted, but clearly, more long-term studies and more patients are required to evaluate the actual safety concerns.

### IL-6 Inhibitors

Tocilizumab is a fully human monoclonal antibody directed against the IL-6 receptor, and it is highly effective in sJIA and polyarticular-course JIA patients.[115-117] Similar to canakinumab and rilonacept, tocilizumab showed remarkable efficacy in sJIA. In a RCT, tocilizumab was safe and efficacious in biologic-naïve and biologic-refractory patients, comparable to the efficacy of etanercept and adalimumab, in polyarticular-course JIA patients.[90-118] Those patients with polyarthritis receiving concomitant MTX and tocilizumab had better responses compared with those without MTX. Patients who had previously taken biologics had poorer ACR responses than biologic-naïve patients, showing more treatment-resistant disease. As with the other newer biologics, the numbers of patients exposed are small, making it difficult to assess the safety profile. Infection, neutropenia, and reversible transaminitis were noted in both trials, with mild to moderate elevation of low-density lipoprotein and cholesterol levels in the trial with polyarticular-course JIA patients.

## Other Disease-Modifying Anti-rheumatic Drugs and Biologics

Rituximab may be considered as a treatment option for patients who have not responded to other therapies and continue to have high, refractory disease activity based on adult RA studies, limited observational studies, and case reports in children.[66,119] An open-label, multicenter RCT comparing combination DMARDs (MTX, SSZ, and hydroxychloroquine) versus MTX and infliximab versus MTX alone in early diagnosed polyarticular-course JIA patients showed that MTX and infliximab was the most effective.[120] The following paragraphs discuss specific JIA subtypes and their recommended treatments.

# TREATMENT OF JUVENILE IDIOPATHIC ARTHRITIS SUBTYPES

## Treatment of Oligoarticular Juvenile Idiopathic Arthritis

Treatment of patients with arthritis in four or fewer joints is usually approached in a stepwise fashion (Figure 107-2).[66,121] Poor prognostic features include involvement of the hip or cervical spine; ankle or wrist involvement with high inflammatory markers; or radiographic changes, such as erosions and joint space narrowing.[66]

## Treatment of Polyarticular Juvenile Idiopathic Arthritis

Treatment approaches are similar for patients with arthritis in five or more joints, regardless of JIA subtype with the exception of sJIA (see Treatment of sJIA section). Children with polyarthritis require a DMARD such as MTX as soon as practically possible after the diagnosis has been confirmed, if they have high disease activity or if there is moderate activity with poor prognostic features. Poor prognostic features include arthritis of the hip or cervical spine, positive RF or ACPAs, and radiographic damage. If NSAIDs are initially used as monotherapy, with or without IAS, continued disease activity for no more than 1 to 2 months should prompt escalation of therapy, as shown in Figure 107-3.[66] Per the ACR guidelines, MTX is the first DMARD of choice, and if there is an inadequate response to MTX by 3 months with continued moderate or high disease activity, TNF inhibitors should be added corresponding to the "Step Up" arm of the consensus treatment protocol.[66,86,90] The different TNF inhibitors have not been directly compared, so it is not possible to determine which might be most effective and safe in a given patient. After 4 months of TNF inhibition, if there is still moderate or high disease activity, the ACR guidelines recommend switching to

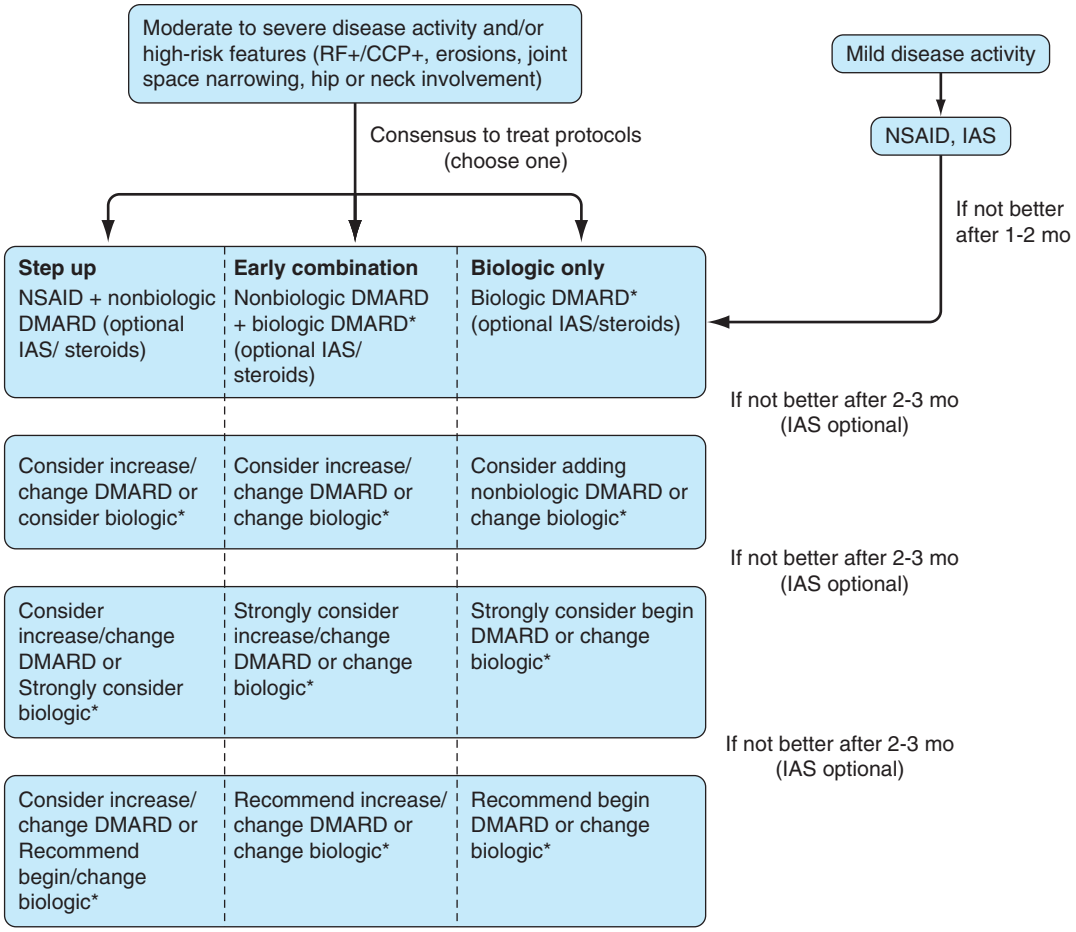

**Figure 107-3** Treatment algorithm for patients with juvenile idiopathic arthritis (JIA) with polyarthritis or arthritis in five or more joints. another TNF inhibitor or to another biologic, such as abatacept.[66,121] However, with sequential use of biologics, the response rate is attenuated.[122] Rituximab, tocilizumab, abatacept, or different combinations of various DMARDs and biologics have all have been used after failure of response to TNF inhibitors, with varying degrees of success.[66,121]

Because children with $RF^+$ polyarticular JIA are at higher risk of prolonged erosive arthritis compared with other subtypes of JIA, these children should be considered to be in the more severe disease category, requiring rapid escalation of treatment if even mild disease activity persists.[66]

SSZ and leflunomide can be used before a TNF inhibitor in mild disease, although evidence suggests that leflunomide may be slightly less effective than MTX.[123] SSZ is more typically used with HLA-B27–associated arthritis and JSpA.

In 2012, an RCT called Trial of Early Aggressive Therapy (TREAT) compared two aggressive treatment arms (combination of corticosteroids and etanercept, and MTX vs. MTX alone) for patients with active polyarticular JIA within 1 year of diagnosis. There was a trend toward improvement in the MTX, etanercept, and prednisone arm, and it showed that CID[124] at 6 months was attainable by using either of the two early aggressive treatment arms. This study also suggested a treatment window of opportunity: The shorter the disease duration before treatment, the higher the likelihood of reaching CID at 6 months (odds ratio [OR] per month, 1.3, $P < 0.011$).[125,126] However, 65 % of children were not able to sustain CID beyond 6 to 12 months, especially with medication taper,[127] suggesting that longer therapy may be helpful.

## Treatment of Juvenile Spondylitis

To date, there have been few studies or trials on JSpA. One study of SSZ showed no significant effects in JSpA, whereas another showed good response in JIA patients with oligoarticular and polyarticular course.[128,129] For severe symptoms or evidence of potential joint damage (such as erosive sacroiliitis), the use of TNF inhibitors has been effective based on small pediatric studies and adult studies.[130,131,26,132] The 2011 ACR treatment recommendations for JIA as described previously can be applied to JSpA, taking special note that evidence of active sacroiliitis should be considered a feature of poor prognosis, thus potentially progressing to biologic initiation more quickly.[66]

## Treatment of Juvenile Psoriatic Arthritis

There have been only two open-label prospective studies examining the efficacy of biologics in JPsA, both of which showed improved response within 3 months.[96,133] A study comparing treatment regimens of patients with JPsA versus oligoarticular JIA patients and polyarticular JIA patients found no difference in use of NSAIDs, MTX, and TNF inhibitors.[48] In general, the treatment of JPsA should follow the treatment approaches for patients with oligoarthritis or polyarthritis. MTX is of benefit for both the skin psoriasis and arthritis and in children.[43] In children with more aggressive or axial disease, TNF inhibitors (which have also been successful in treating psoriasis) is indicated and may significantly limit bony destruction.[44,134,135]

## Treatment of Systemic Juvenile Idiopathic Arthritis

sJIA is an active area of research with increasing understanding of the autoinflammatory biology and the potential therapeutic roles for targeted biologics. Therapies such as MTX and TNF inhibitors are less helpful in sJIA compared with other forms of JIA.[52,136-138] An approach to treating sJIA is shown in Figure 107-4, separating this complex disease into different severities and manifestations. This algorithm is consistent with the recently published 2013 ACR guidelines for sJIA,[67] consensus treatment plans for sJIA,[68] and published RCTs.[114,115] Mild sJIA, defined as mild systemic symptoms and synovitis without organ system involvement, can be successfully treated with anti-inflammatory doses of NSAIDs. Certain NSAIDs are helpful for different aspects of the disease (e.g., indomethacin can be used for fever control and serositis symptoms). In addition, if there are only a few large joints involved, IASs are an additional option.
